Development of Three-Dimensional Object Completion in Infancy

Kasey C. Soska
New York University

Scott P. Johnson
University of California, Los Angeles

Three-dimensional (3D) object completion was investigated by habituating 4- and 6-month-old infants (n = 24 total) with a computer-generated wedge stimulus that pivoted 15°, providing only a limited view. Two displays, rotating 360°, were then shown: a complete, solid volume and an incomplete, hollow form composed only of the sides seen during habituation. There were no reliable preferences for either test display by 4-month-olds. At 6 months, infants showed a reliable novelty preference for the incomplete test display. Infants in a control group (n = 24) not habituated to the limited-view wedge preferred neither test display. By 6 months, infants may represent simple objects as complete in 3D space despite a limited perspective. Possible mechanisms of development of 3D object completion are discussed.

Piaget (1954) pioneered the study of infants' perceptual and cognitive abilities with his foundational work on object knowledge and spatial cognition. Since these original studies, a wealth of information on visual-cognitive abilities has accrued in such areas as object permanence (e.g., Baillargeon, 1987; Diamond, 1990), spatial reasoning (e.g., Bremner, 1978; Rieser, 1979), and perceptual completion (e.g., Johnson, Bremner, et al., 2003; Kellman & Spelke, 1983). Departures from the age and motor constraints Piaget suggested originally have been claimed, sparking polemic arguments on the "true" capacities of young infants (Spelke, 1998).

Modern rationalist views of infants' understanding of the physical world have contended that infants are more sophisticated in their representations of the visual world than Piaget surmised (Spelke, Breinlinger, Macomber, & Jacobson, 1992). Studies examining infants' understandings of object continuity and solidity, for example, have suggested that infants as young as 2.5 months may have a rudimentary understanding of object permanence (Aguiar & Baillargeon, 1999). In general, those arguing in favor of the precocious nature of infants' object perception and physical understanding maintain that developmental processes are more related to infants' sensitivity to relevant features of the objects used in the displays rather than changes in the underlying mechanisms of information-processing and object knowledge (e.g., Baillargeon, 2004).

Others have argued for a more gradual emergence of object knowledge over the 1st year after birth—with infants' understanding of the physical world built upon successively more sophisticated attentional skills, an increasing ability to integrate multiple sources of information in the visual array, and emerging manual and other exploratory skills to facilitate the acquisition of physical knowledge (e.g., Colombo, 2001; Gibson, 1988; Johnson, 2003). Work on infants' perception of causality (e.g., Cohen & Oakes, 1993), perception of object unity (e.g., Johnson, 2004), and object recognition (e.g., Kraebel & Gerhardstein, 2006) has provided evidence for infants' gradually emerging object knowledge. The present study, therefore, was motivated by this growing awareness of the importance of understanding developmental processes in providing a more accurate account of infants' physical world than is offered by rationalist approaches.

We examined infants' perception of the full, volumetric form of three-dimensional (3D) objects when provided only a limited view, asking if infants represent objects seen from a limited vantage as coherent volumes or instead as consisting solely of the surfaces that are visible from the current viewpoint. This question maps onto work investigating developmental processes of object and spatial knowledge and relates to work on perceptual completion in general in infancy.

This research was supported by the National Institutes of Health Grant R01-HD40432. Portions of this work were presented at the 2006 meeting of the Vision Sciences Society, Sarasota, FL, and the 2006 International Conference on Infant Studies, Kyoto, Japan. We gratefully acknowledge the infants and parents who participated in the studies. We also thank Juliet Davidow, Melissa Rozon, and Lauren Clepper for their help in recruiting infant participants, and we thank Holly Hamilton and Alissa Gaughan for their assistance with reliability coding.

The 3D nature of our world may pose a challenge to the immature visual system. Distant objects are often occluded by nearer objects, and recognition of the partially occluded object requires synthesis of the visible portions into a coherent percept. Objects come in and out of existence as they move or observers move around them, and the far sides of opaque objects are blocked from sight by their visible portions—the problem of self-occlusion. Despite the fragmented nature of the visual world, adult observers are adept at discriminating and recognizing complete forms through spatial and spatiotemporal occlusion (Kellman & Shipley, 1991; Marr, 1982) and through self-occlusion (Tse, 2002). Thus, our visual experience is not composed of disjoint surfaces, fleeting percepts of moving objects, and incomplete, hollow volumes; rather, our visual system "fills in" the missing parts, resulting in a richer experience than what is visible directly.

The visual system of the adult is able to accomplish perceptual completion under many circumstances without apparent effort, but the visual experience of very young infants is substantially different. Four-month-olds perceive a moving, center-occluded rod as a unified object rather than two disjoint segments (Kellman & Spelke, 1983), but newborn infants perceive this display as consisting of unconnected pieces (Slater, Johnson, Brown, & Badenoch, 1996). In these investigations, infants were habituated to a display in which a rod moved laterally behind an occluder. After habituation, infants were shown two test displays, both without the occluding box: one depicting a complete, unbroken rod and in the other, two broken rod pieces of the same size as the visible portions seen previously. Consistently longer looking at either test display is interpreted as a novelty response; therefore, a posthabituation preference for the broken rod pieces would imply unity perception during habituation. Newborns preferred the unbroken rod at test, whereas older infants preferred the broken rod parts.

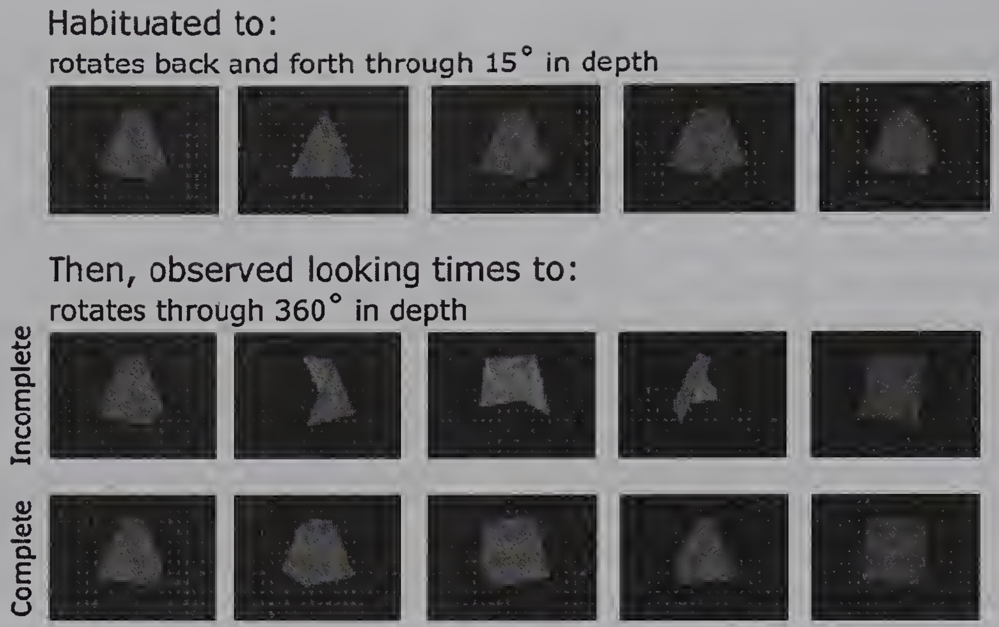
Other experiments examined spatiotemporal completion: the perception of occluded trajectories of moving objects. When shown a display in which a ball moves back and forth, the center portion of its trajectory occluded by a box, infants at 6 months appeared to perceive the ball continuing behind the occluder, both in an habituation experiment (Johnson, Bremner, et al., 2003) and in an oculomotor anticipation paradigm (Johnson, Amso, & Slemmer, 2003), but younger infants provided evidence of perceiving the visible parts of the trajectory only, failing to complete it, in parallel with experiments on perception of object unity described previously. Infants' visual cognition thus undergoes substantial development during the first few months after birth toward an experience of a more holistic percept of the visual environment.

These and other experiments have characterized infants' perception of spatial and spatiotemporal unity. In contrast, little is known about how infants come to understand self-occlusion and perceive volumetric unity. Work on the development of 3D object completion and infants' understanding of self-occlusion may help elucidate how the infant's visual system overcomes the problems imposed on it by the cluttered 3D world as well as further general learning principles.

A subsidiary goal of the present work is to understand better the nature and limits of 3D form perception in young infants. Early research showed that 4-month-olds could discriminate familiar objects in novel axes of rotation from novel rotating objects (Kellman, 1984). Infants in these experiments, however, could not generalize 3D form across views within static displays and required either object or observer movement to discriminate novel and familiar objects (Kellman & Short, 1987). Infants as young as 2 months are adept at picking up 3D structure from kinetic information (Arterberry & Yonas, 2000), and by 4 months, infants are sensitive to some pictorial cues that signify 3D structure (Bhatt & Bertin, 2001; Bhatt & Waters, 1998; Shuwairi, Albert, & Johnson, 2007). Infants at 2 and 4 months will complete a 3D shape when occluded in displays depicting fully rotating 3D forms (Johnson, Cohen, Marks, & Johnson, 2003). Recent work from an operant learning paradigm provides evidence that at 3 months, infants may achieve view-invariant 3D object recognition when given the opportunity to cause the movement of various 3D forms (Kraebel & Gerhardstein, 2006).

Together, this work on perceptual completion and 3D object perception shows that young infants by 4 months show some nascent understanding that objects are continuous in space and that most objects are 3D. Infants appear to continually build upon their existing knowledge and attentional skills to visually complete more complex displays and veridically perceive more complex objects. Still, it is not known when and how infants come to perceive a complete 3D volume through self-occlusion.

In the present experiment, we showed infants computer-generated displays depicting objects rotating in depth around the vertical axis (see Figure 1)—either pivoting back and forth through 15° (*limited view*) or rotating through a full 360° (*full view*). Infants were shown a limited-view display during habituation, providing the opportunity to see only a few faces of the object. Once infants met the habituation criterion, they were shown two new full-view displays.



Habituated to:
rotates back and forth through 15° in depth
Then, observed looking times to:
rotates through 360° in depth
Incomplete
Complete

Figure 1. The visual stimulus set.
Note. Infants were habituated to a wedge-shaped object that rotated back and forth 15° around the vertical axis. During test, infants viewed a complete and an incomplete version of the object on alternating trials, both rotating through 360°.

One display depicted a complete solid object, and the other depicted an incomplete hollow object composed of only the surfaces seen during habituation. All the displays contained rich information for 3D form including kinetic cues (e.g., relative motion, contour deformation) and pictorial cues (e.g., shading, line junctions). We reasoned that if an infant perceived the limited-view object as complete during habituation, then during test he or she should respond to the incomplete display as novel and thus look longer at it than at the complete display. If, however, the infant showed no reliable preference for either display following habituation, then we reasoned that infant likely did not perceive the self-occluded surfaces of the limited-view object.

We tested infants at 4 and 6 months to explore developmental differences in performance. To assess whether infants in these age groups show any spontaneous preferences for incomplete or complete 3D objects, infants in a control group were shown complete and incomplete test displays without first being habituated to the limited-view object.

Method

Participants

The final sample consisted of twenty-four 4-month-olds (*M* age = 118.4 days, *SD* = 12.8) with 11 males and 13 females and twenty-four 6-month-olds (*M* age = 179.3 days, *SD* = 9.4) with 12 males and 12 females. Additional infants were observed but excluded from the analyses due to fussiness (9 infants), consistent inattention toward the screen (6 infants), parental interference (2 infants), or experimenter error (2 infants). Participants were recruited via letter and phone using a marketing database containing the names of parents with young children. The majority were from Caucasian, middle-class families in the New York City metropolitan area. All parents were fully debriefed about the experimental procedure and informed consent was obtained before beginning the session.

Apparatus and Stimuli

Infants were tested individually and seated on their parent's lap 120 cm from a 76-cm monitor in a darkened room. An experimenter was hidden behind a divider and operated a Macintosh computer that performed several functions. The computer presented the stimulus displays, stored each infant's data, calculated the habituation criterion for each infant, and changed displays after the criterion was met. The computer also recorded how long each infant looked at each display, according to the experimenter's judgments.

The displays depicted a computer-generated wedge (Figure 1). Each shape subtended a maximum visual angle of 8.5° (height) and 11.5° (width). During habituation, the object rotated 15° back and forth around the vertical axis. It took 4 s to complete a pivot in both directions and return to center. At test, following habituation, the complete object was the simplest interpretation of the limited-view object: a symmetrical mirror of the faces seen originally.

The incomplete object was composed of only the faces seen during habituation. In test displays, it took 10 s for the object to make a full rotation. The objects were covered with a brown, wood-like surface and presented against a background consisting of a 12 × 20 grid of white dots, which covered the entire monitor. Informal pilot testing revealed that all the displays were interpreted as rotating 3D objects by adult observers.

Procedure

Each trial began with the presentation of an attention-getter (a looming and contracting ball accompanied by a repetitive sequence of tones) to attract the infant's attention to the screen and center the point of gaze. Once the experimenter determined that the infant had fixated the screen, the attention-getter was replaced with the experimental stimulus and timing of each trial began. A trial ended when the infant looked away for 2 s or until 60 s of total looking had accumulated; the attention-getter was then shown again, immediately followed by a new trial. The habituation display (the limited-view object) was presented until the infant met a habituation criterion: a decline in looking time during four consecutive trials adding up to less than half the total looking time during the first four trials. Upon meeting the criterion, the infant was shown the test displays starting on the next trial. Consequently, there was a minimum of five habituation trials, and the maximum number of trials was set to be 12. The two test displays were seen in alternation three times each—for a total of six posthabituation trials. In the control task, the procedure was the same except infants were not habituated to the limited-view object display first. Instead, infants only saw the two test displays in alternation three times each. Infants were randomly assigned to one of the two test display orders (incomplete first or complete first) and to the habituation task or no-habituation control.

To assure reliability of the experimenter's judgments, an independent observer coded looking times off-line for 25% of the sample. The Pearson correlation between the experimenter's and the coder's judgments of the total looking time on each trial was .93, indicating strong agreement between the on-line and off-line coding.

Results

Data consisted of looking times toward the two displays at test. Before analysis, the data were logarithmically transformed due to excessive skew in some cells that violated the assumptions of the analysis of variance (ANOVA)—data in the figures are based on nontransformed scores. Preliminary analyses revealed there were no notable differences in looking times based on sex of infant or order of test display presentation, so these factors were not included in further analyses.

Figures 2 and 3 show looking-time results of 4- and 6-month-olds, respectively. A 2 (age: 4 or 6 months) × 2 (condition: habituation or no-habituation control) × 2 (test display: complete or incomplete object) × 3 (test trial block: first, second, or third) mixed-design ANOVA was performed—with age and condition as between-participant factors and test display and test trial block as within-participant factors. The analysis revealed a significant main effect of condition, $F(1, 44) = 16.58$, $p < .001$, partial $\eta^2 = .274$, due to greater looking overall by infants in the control condition; a significant main effect of test display,

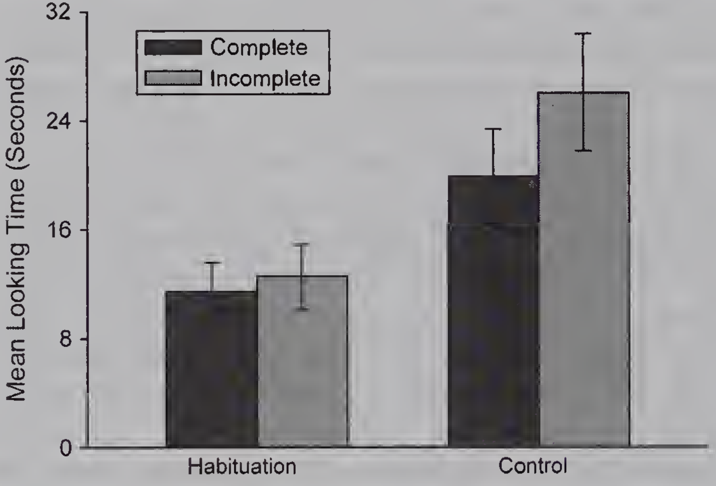


Figure 2. Looking-time results of 4-month-olds.
Note. Error bars represent standard error of the means.

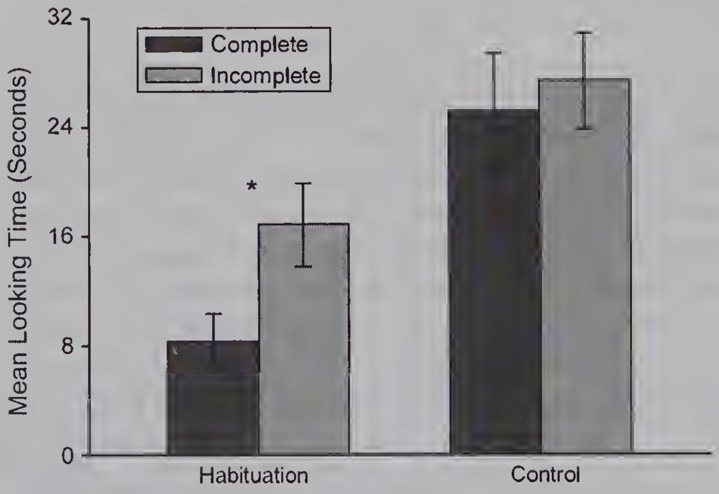

Figure 3. Looking-time results of 6-month-olds.
Note. Error bars represent standard error of the means.

$F(1, 44) = 25.11$, $p < .001$, partial $\eta^2 = .363$, due to greater looking overall at the incomplete object; and a significant main effect of test trial block, $F(2, 88) = 26.89$, $p < .001$, partial $\eta^2 = .379$, due to an overall decline in looking across test trials. This latter effect was mediated by a reliable Test Trial Block × Condition interaction, $F(2, 88) = 3.83$, $p < .05$, partial $\eta^2 = .08$, stemming from a greater decline in looking across trials by infants in the control condition.

Most important, there was a reliable three-way interaction of age, condition, and test display, $F(1, 44) = 5.11$, $p < .05$, partial $\eta^2 = .104$. Further analyses indicated that this three-way interaction was due to the presence of a significant Condition × Test Display interaction for the 6-month-old infants, $F(1, 22) = 12.00$, $p < .01$, partial $\eta^2 = .353$, but not for the 4-month-old infants, $F(1, 22) = .035$, *ns*, partial $\eta^2 = .002$. Separate pairwise comparisons in the habituation and control conditions revealed that 4-months-olds showed no reliable preference for either test display, $t(11) < 2.2$, $p > .05$ (see Figure 2). Infants at 6 months of age in the control task showed no preference for either test display, $t(11) = 0.836$, *ns*, though 6-month-old infants in the habituation condition reliably preferred the incomplete display, $t(11) = 6.16$, $p < .001$ (see Figure 3).

We conclude that infants at 4 months do not perceive completion of the self-occluded surfaces in limited-view objects. Although previous work has indicated that 4-month-olds may be sensitive to both kinetic and static cues to depth (Arterberry & Yonas, 2000; Bhatt & Bertin, 2001; Kellman, 1984; Shuwairi et al., 2007), infants at this age provide no evidence of sensitivity to the full, volumetric forms of limited-view 3D objects under the conditions we provided. Results of 6-month-olds, in contrast, provide positive evidence for 3D object completion in this age group.

Discussion

We investigated developments in 3D object completion: perception of objects as volumetric and complete in 3D space when only a limited vantage point is available. We habituated infants at 4 and 6 months to displays depicting objects rotating through 15°. During test, infants were shown alternating displays depicting objects, either complete volumes or hollow facades, rotating through 360°. If infants perceived a complete volume with self-occluded surfaces while viewing the limited-vantage object, we reasoned that the incomplete test display should have been experienced as novel and therefore recruit increased looking times relative to the complete display. The 4-month-olds preferred neither test display, providing no evidence for 3D object completion at this age, but 6-month-olds showed reliably longer looking times to the incomplete test display. These older infants provided evidence for perceptual completion of the limited-view stimulus, inferring the existence of self-occluded surfaces. Infants at both 4 and 6 months of age who were not first habituated to the limited-view object showed no reliable preferences for either display—implying that intrinsic preferences for incomplete objects can be excluded as an alternative explanation of infants' performance during the habituation tasks.

Thus, we have evidence for a developmental progression of infants' 3D object completion abilities, strengthening the view that object knowledge emerges gradually over the 1st year after birth. Between 4 and 6 months of age, infants seem to become increasingly proficient at forming percepts of complete volumes. The period around 6 months appears to represent a transitional period in the development of this visual-cognitive skill, as infants' nascent volumetric completion abilities are first becoming evident. Although it is clear that the rudiments of 3D object completion emerge around 6 months of age, further developments in this ability may relate to the complexity of the 3D forms used during testing.

These findings provide evidence regarding the time course of infants' perception of complete forms through self-occlusion to accompany the sizable literature on infants' and adults' perceptual completion abilities (e.g., Johnson, 2004; Kellman & Shipley, 1991; Tse, 2002). More than simply perceiving and registering the visible elements in a scene, perceptual completion through various types of occlusion (Johnson, Bremner, et al., 2003; Kellman & Spelke, 1983) involves the workings of sophisticated and complex mechanisms that fit together the visible parts of the world to form sensible holistic forms. 3D object completion is a perceptual inference that requires infants to recognize the unified and reversible aspects of an object in space.

Understanding the development of 3D object completion in infancy shapes a framework of how object knowledge and perception emerge over the 1st year after birth. Insights into the general processes of development can be gained, as this collective work on visual completion can help inform theories of cognitive development. For example, previous work on infants' visual completion provides strong support for a constructivist view of perceptual development (Johnson, 2003, 2004). Continually more complex forms are derived from the processing of smaller units that are assembled into a fuller percept. The experiments presented here add to this body of knowledge, by showing that 3D object completion perception may be built out of lower perceptual knowledge—kinetic and pictorial information for three dimensionality. Interestingly, infants at around 6 months of age also begin to use similarity of form to organize abstract visual patterns (Quinn, Bhatt, Brush, Grimes, & Sharpnack, 2002). Perhaps bottom-up configural processing, such as grouping by form, is developing in tandem with experiential components, supporting more sophisticated object perception such as volumetric completion.

One possibility is that infants around 6 months, who show the first evidence of 3D object completion, may also be starting to tune into the relevant features of 3D objects during normal visual experience. An object recognition system emerging during the middle of the 1st year (Colombo, 2001) may guide infants' information-processing and attentional allocation. Another possibility builds on Piaget's (1954) proposal that object knowledge is constructed in tandem with the increasing coordination of action systems. The present work on 3D object completion has discovered a perceptual ability whose onset is commensurate with the 5- to 6-month age range during which coordinated visual-manual exploration of objects is known to arise (Eppler, 1995; Rochat, 1989). As they play, infants may discover that objects have hidden surfaces, revealed via rotation, and build up volumetric completion from these explorations.

Young Children's Recognition of the Intentionality of Teaching

Margalit Ziv and Ayelet Solomon
Tel Aviv University

Douglas Frye
University of Pennsylvania

Two studies examined the role of intention in preschoolers' understanding of teaching. Three- to 5-year-olds judged stories in which there was an intention to teach or not (teaching vs. imitation) for 4 different learning outcomes (successful, partial, failed, and unknown). They also judged 2 stories with embedded instructional intent (e.g., guided discovery learning) and several standard theory of mind tasks. There was an age-related change in the understanding of teaching. Five-year-olds distinguished teaching from imitation and recognized guided discovery learning. Understanding of imitation and false belief was related. The findings indicate that theory of mind is relevant to other means of knowledge acquisition besides perceptual access and that understanding intention could help young children to recognize instruction and identify its different forms.

Developmental psychology's recent, intense interest in children's theory of mind has provided new insights into how young children understand knowledge and the ways in which it is acquired. Preschool theory of mind can be seen as the first step in a series of changes in the understanding of knowledge (Kuhn, 2000; Montgomery, 1992; Olson & Bruner, 1996). The numerous studies that have concentrated on the basic step of false-belief understanding (see Flavell & Miller, 1998, for a review) have now shown that 5-year-olds have a different grasp of knowledge than children just 2 years younger because they realize that mistakes in representation are possible (Wimmer & Perner, 1983).

More is involved in this change in theory of mind than just the recognition of the different mental state of false belief. There is also a change in the understanding of *how* knowledge is acquired. Preschoolers gain a better understanding of perception as a means of acquiring knowledge (Pillow, 1989; Povinelli & deBlois, 1992; Taylor, 1988; Wimmer, Hogrefe, & Sodian, 1988). In the typical false-belief situation, 5-year-olds realize that it is because of a lack of perceptual access that someone will be mistaken about the location of an object or contents of a container. Three-year-olds, even though they notice the lack of perceptual access, do not seem to use the information to draw this conclusion.

New research in theory of mind has now widened the investigation of both types of knowledge and forms of knowledge acquisition young children understand. Miller (2000) integrates the findings on children's understanding of differences in many kinds of knowledge, not just false belief. Understanding of other forms of knowledge change is being studied for inference (Pillow, 1999; Sodian & Wimmer, 1987), communication and testimony (Beal, 1988; Clement, Koenig, & Harris, 2004), learning (Sobel, Li, & Corriveau, 2007), and teaching (Astington & Pelletier, 1996; Kuhn, 2000; Olson & Bruner, 1996; Strauss, Ziv, & Stein, 2002; Ziv & Frye, 2004).

Several questions are important regarding these other forms of knowledge acquisition. Accounting for young children's understanding will require finding out which forms of knowledge acquisition they grasp beyond the established "seeing leads to knowing" of perception. It will also be useful to know whether they gain an understanding of these other forms at about the same time as perception or only later. Last, because the forms do differ and may involve different mental states, it will be important to begin to determine how children identify any given one of them.

Teaching is a common way for children to acquire knowledge. It is known that even 3-year-olds refer to teaching, although not with high frequency (Bartsch, Horvath, & Estes, 2003; Sobel et al., 2007). From the standpoint of theory of mind, teaching can be defined as an intentional activity to increase the knowledge or understanding of another (Frye & Ziv, 2005). This approach extends previous analyses of the mental

state aspects of teaching. Olson and Bruner (1996) state that in order to teach a person needs a theory of mind to recognize the lack of knowledge in others. Thus, awareness of a difference in knowledge is a prerequisite for teaching. Kruger and Tomasello (1996) emphasized that teaching involves intention and that it can only be adequately defined by its goal. The intent in teaching is that another person learns a new skill, acquires knowledge, or deepens his or her understanding.

The need to understand knowledge states to identify teaching has been recognized. Olson and Bruner (1996) predicted that false-belief understanding should be integral to teaching. If young children do not understand when people lack or are mistaken in their knowledge, they presumably will not be able to identify the conditions under which teaching will occur. Furthermore, they will have to make this judgment from the teacher's point of view. Teaching will not occur whenever a student misunderstands something. It is only when the misunderstanding is recognized by the one furnishing the knowledge that instruction can take place.

Ziv and Frye (2004) found empirical support for this analysis. It was established that both 3- and 5-year-olds were able to indicate that teaching would be directed toward someone who lacked knowledge about how to do something and not toward someone who knew how, and that only a knowledgeable person can assume the role of teacher, even in the instance of a child teaching an uninformed adult. Only the 5-year-olds, however, seemed able to judge the situation from the teacher's perspective and could identify teachers' beliefs about learners' knowledge. For example, only the 5-year-olds recognized that teaching would not take place when the teacher thinks a student knows how to do something, but the person really does not. The overall results showed that after 3 years, children understand that a difference in knowledge between two parties is necessary for teaching. After 5 years, they further understand that it is the teacher's belief about the knowledge difference that will actually govern teaching. This success was correlated with an understanding of false belief.

Strauss et al. (2002) presented a subset of these same tasks and found that the instructional strategies children employed during peer teaching were associated with the children's own understanding of knowledge states. Children were taught a simple board game and asked to teach and then play it with a same-aged peer. The 3-years-olds taught the peer how to play the new game by demonstrating and modeling. They also had difficulty understanding mistaken judgments of students' knowledge in the teaching stories. In contrast, 5-year-olds employed more advanced verbal teaching strategies, which included asking students about their understanding. In addition, they showed good comprehension of the theory of teaching tasks. These results are consistent with other tests of young children's teaching strategies (Ashley & Tomasello, 1998; Davis-Unger, 2008; Wood, Wood, Ainsworth, & O'Malley, 1995) and with the findings that children tend first to talk about teaching as showing and then shift to describing it as telling or explaining (Astington & Pelletier, 1996).

The relevance of intention for identifying teaching has not been empirically studied, but a theoretical basis for it exists. Kruger and Tomasello's (1996) characterization of teaching as an intentional activity builds on prior approaches to the topic (Macmillan & McClellan, 1968). Nonetheless, there are current definitions of teaching in psychology that do not include intention. For example, Caro and Hauser (1992) have argued for a functional definition. They state that teaching occurs when one party modifies his or her behavior, without direct reward, in the presence of another and that the change improves the other's learning compared to what would have occurred otherwise.

The intentional and functional definitions differ in what activities will be identified as teaching. The intentional definition also makes at least one distinction among different forms of knowledge acquisition that is not made by the functional one. Depending on which definition describes young children's concept of teaching, they should only classify certain activities as instructional. For example, the intentional definition makes it possible to separate the goal from the outcome in teaching, and therefore it still identifies the activities that occur in unsuccessful teaching as a part of teaching. According to the functional definition, the learner's behavior must change as a consequence of the teacher's behavior. Therefore, it excludes instances in which teaching was attempted but was not successful and, consequently, must identify teaching retrospectively.

Intention also establishes a distinction between teaching and imitation as distinct forms of knowledge acquisition. Imitation occurs when a novice observes a knowledgeable person do something and, as a consequence, learns how to do the same thing. This process can be distinguished from teaching. An indication of the difference is that imitation can take place even when the expert has no idea that the novice is watching. The outcome can be exactly the same in both teaching and imitation; therefore, the difference is not a functional one but instead depends on intention. In teaching, the expert presents events *in order* to change the understanding of the novice, and those choices will not be made if the expert is unaware of the novice's presence.

If children rely on intention to understand what teaching is, then developmental changes in the understanding should be apparent. Preschoolers' understanding of intention is regarded an essential component of their developing theory of mind (Astington, 1991; Malle, Moses, & Baldwin, 2001; Zelazo, Astington, & Olson, 1999). Several studies have investigated when children begin to recognize intention. The studies often concentrate on children's ability to distinguish between an intentional and nonintentional act as well as between the intention that underlies people's behavior and the outcome of that behavior (Astington, 1991; Feinfield, Lee, Flavell, Green, & Flavell, 1999; Karniol, 1978; Moses, 1993).

Astington and Lee (1991), for example, had children listen to two stories. In the first story, a girl asks her mother for some breadcrumbs, takes the crumbs outside, and throws them to the birds, who then eat them. In the second story, another girl asks her mother for a sandwich, which she takes outside to eat, but some crumbs accidentally drop behind her, and the birds eat them. The two stories have the same outcome, caused in both cases by the child's behavior, but the intention to feed the birds is only present in the first. When children were asked which girl meant to feed the birds, 3-year-olds were equally likely to choose either girl. In contrast, 5-year-olds correctly said that it was the girl who asked for the crumbs and threw them at the birds who meant to feed them.

The judgments of the 3-year-olds were interpreted as reflecting a matching strategy (Shultz & Wells, 1985). This strategy simply assumes that an outcome is intentional if it is in accord with a person's goal or existing desire and unintentional if it is not. In other words, 3-year-olds understand simple goal-directed action. They are capable of determining when a familiar action has a goal and whether the goal has been fulfilled or not (Shultz & Wells, 1985; Wellman & Woolley, 1990). However, they do not yet appreciate the crucial distinction between intention and outcome and tend to assign more weight to the outcome than to the intention when judging whether a behavior is intentional or not.

A matching strategy would not allow children to appreciate that a desirable outcome, which occurs accidentally is unintentional (Astington, 1991). Schult (2002) found that accidental outcomes were the most difficult judgment about intention for 3- and 4-year-olds to make. The 3-year-olds in particular seemed to judge intention by an act's failure or success. On the other hand, Astington and Lee's and Schult's results indicate that older preschoolers are beginning to appreciate that judging the intentionality of an act does not depend on its outcome and that desired outcomes can be caused by either intentional or nonintentional acts.

The current two studies test whether children consider intention in understanding what teaching is, and hence how theory of mind may be relevant to an additional form of knowledge acquisition besides perceptual access. The first study explores the role of intention versus outcome in children's judgment of teaching. The second study then elaborates on the relations between children's understanding of intention and their developing concept of teaching.

In the first study, new tasks were designed in which the knowledge conditions for teaching were kept constant. In all the stories, there was an experienced person who knew how to do something and an inexperienced person who did not. The tasks then varied the intention–outcome relation to explore children's understanding of the role of intention as a mediating link between the knowledge difference necessary for teaching and the outcome of the interaction. The stories differed either in intention—whether the intention to teach was present or not—or in outcome—whether learning occurred or not.

One pair of tasks examined whether the presence of the intention to teach is an important consideration for young children in judging what teaching is and if it can be considered apart from the outcome of teaching. A story in the pair described teaching that successfully results in learning. The other described a child who successfully learns a new skill by imitating an expert, when it is clear that the expert is unaware of the learner. Thus, there is no intention to teach, but learning is accomplished. If children rely on intention in their judgments, the activity should not be identified as teaching because it does not involve the expert's intention to teach. However, it may be difficult for 3-year-olds to make that distinction given they have previously been shown to be influenced heavily by positive outcomes in their judgments of intentionality.

A second comparison involves cases that are similar in their intention but differ in outcome. The stories were designed to test whether children understand that teaching is defined by the intent to bring about learning, rather than by whether it is successful in fulfilling the goal or not. One story describes a teacher who intentionally teaches but the student does not acquire any new knowledge. Another version gave no information, positive or negative, about the outcome. Lack of understanding of the crucial role of intention, as opposed to the success of the outcome, may make it difficult for 3-year-olds to accept teaching with a failed or unknown outcome as teaching.

Study 1

Method

Participants. Forty-one children from six preschools in Israel participated. There were twenty-one 3- and 4-year-olds (9 boys and 12 girls, M = 46.8 months, range = 41 – 51 months) and twenty 5- and 6-year-olds (7 boys and 13 girls, M = 68.3 months, range = 63 – 74 months). The children were proficient in Hebrew and primarily from middle-class families. None of the families were new immigrants; over 85% of the parents were born in Israel.

Design. There were seven types of stories. An example of each is given in the Appendix. Six of the seven types were related to teaching. The last type assessed false-belief understanding (Wimmer & Perner, 1983). An additional type of teaching task that assessed the understanding of instructional games was also pilot tested. On the basis of this information, a pair of these tasks was incorporated in Study 2. A description of these tasks and their results are presented there.

The teaching-related stories presented different pairings between the agent's intention and the outcome of the agent's act for another's learning. Children were asked to judge whether the agent tried to teach the other character in the story or not. The agent's act either reflected an intention to teach or not. Information regarding the outcome took one of the three forms: learning occurred, learning did not occur, or no information was given about the outcome. Using these features, there were three types of actual teaching stories and three types of imitation stories:

1. Successful teaching. The agent has the intention to teach and learning occurs.
2. Successful imitation. The agent does not have the intention to teach and learning occurs.
3. Failed teaching. The agent has the intention to teach and no learning occurs.
4. Failed imitation. The agent does not have the intention to teach and no learning occurs.
5. Unknown outcome of teaching. The agent has the intention to teach and the outcome is unknown.
6. Unknown outcome of imitation. The agent does not have the intention to teach and the outcome is unknown.

The seventh type of story was an assessment of false-belief understanding in a standard change-of-location format that asked where an uninformed character would look for a displaced object.

Procedure. Because children were asked whether the agent in each story "tried to teach," children's understanding of the phrase "try to" was tested before administering the tasks. An experimenter enacted short scenarios of dolls either trying to do something and not always completing the activity or not attempting to execute the activity at all. Children were then asked which of the characters tried to do the target activity (e.g., ride a bike). The majority of children correctly identified both the attempts to perform the activity. Three 3-year-olds erred and were excluded from the study.

Children were presented with 2 stories from each of the seven types for a total of 14 stories per child. The stories were presented across two sessions separated by about a week. One story of each type was given per session. The stories were read in Hebrew and enacted using small male and female plastic figures and a variety of objects in order to reduce the linguistic demands of the tasks. The enactment visually depicted the stories' content, especially the knowledge status or what the characters could do before and after the teaching or imitation situations. Half the stories of each type described the agent performing an academic skill (e.g., writing or counting) and the other half described a nonacademic skill (e.g., tying shoe laces or jumping on one foot). Presentation order of the academic and nonacademic skills was counterbalanced across the participants.

The characters in all the story types were described as children given that preschoolers understand that children can teach in these kinds of stories (Ziv & Frye, 2004). All the stories were counterbalanced for the characters' gender. In one of the stories of each type, the teacher was a female and the learner a male; in the other story, the roles were reversed. Each story included one to three control questions to ensure that children understood the sequence of events and the knowledge status of the story characters at the beginning and at the end of the story. If children were mistaken on the control questions, the experimenter retold the story and repeated the control questions to make certain that the child could answer them correctly. All questions—control and test—were in forced-choice format with the order of the two choices counterbalanced.

The standard change-of-location false-belief task (Wimmer & Perner, 1983) was also presented twice with different materials and characters in order to assess the children's understanding of false belief.

Each false-belief story included two control questions and one test question.

Results

Scoring. Choosing the try-to-teach answer in response to the test question was counted as correct for the successful, failed, and unknown-outcome teaching stories. The did-not-try-to-teach answer was accepted as correct for the successful, failed, and unknown-outcome imitation stories. Prediction of search in the original place was correct in the change-of-location false-belief task.

McNemar tests were employed to compare the two story versions in each task type. The stories for the teaching and imitation tasks had an academic skill and a nonacademic skill version. No difference between versions was found for any of the tasks, so responses were combined, yielding scores that ranged from 0 to 2. All participants correctly answered the control questions regarding the story characters' knowledge status at the beginning and end of the stories.

Age and task differences. The mean percentage correct responses for the two age groups for each of the seven tasks are shown in Figure 1.

The six intention – outcome tasks were analyzed together because they followed a factorial design that examined the intentional (teaching) and nonintentional (imitation) situations for the three outcomes of success, failure, and no information. Correct answers that distinguished teaching from imitation could be given to these stories strictly on the basis of the presence or absence of the intention to teach. Outcome should not have been important because the children were only asked whether the character attempted or *tried* to teach. Nonetheless, the children's responses could have been affected by whether there was a successful, failed, or unknown outcome. Gender had no effect. Therefore, to examine the two potential influences of intention and outcome and to determine whether they affected each other for the two age groups, answers to the test question were analyzed in a 2 (age) × 2 (intention) × 3 (outcome) multivariate analysis of variance (MANOVA) with follow-up analyses of variance (ANOVAs).

The MANOVA found that there was a main effect of age group, $F(1, 39) = 24.03$, $p < .001$, $\eta^2 = .38$, with the 5-year-olds giving a higher number of correct answers overall. There were also two-way interactions between age group and outcome $F(2, 38) = 4.68$, $p < .05$, $\eta^2 = .20$, as well as intention and outcome,

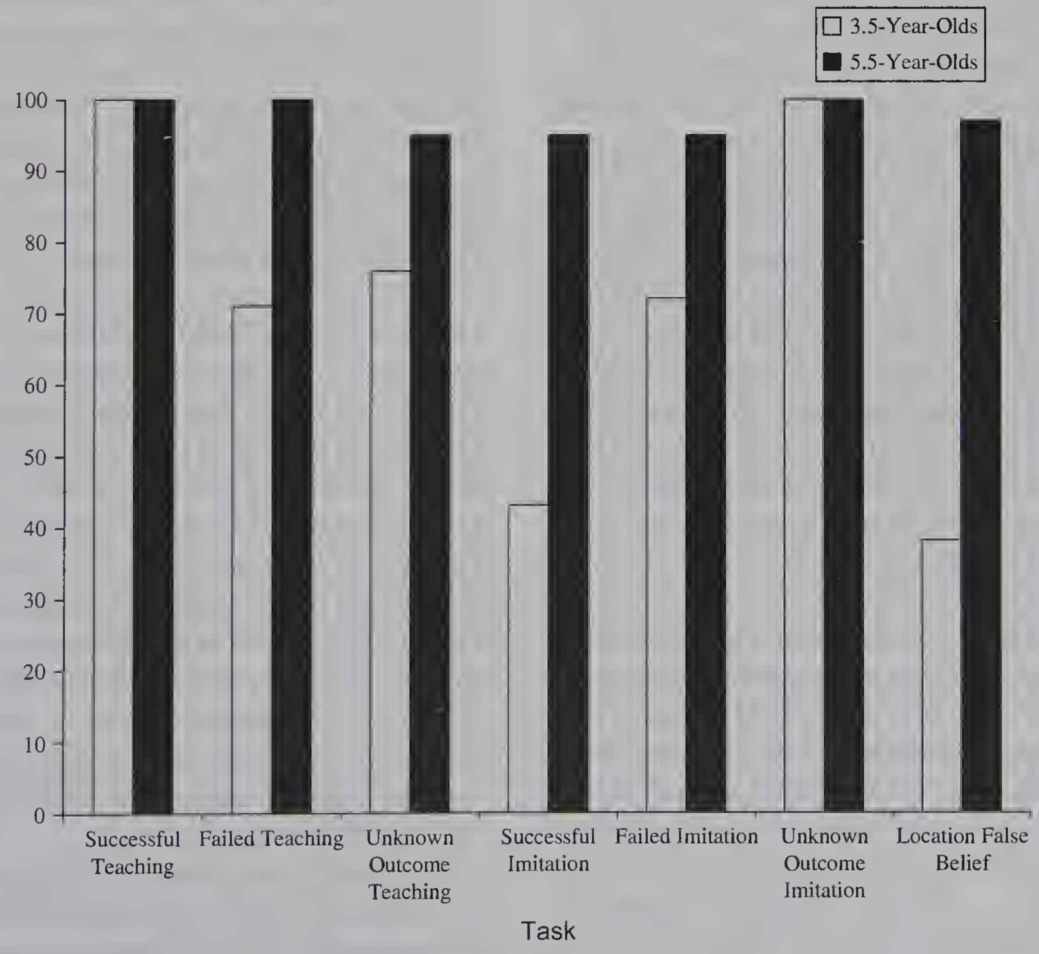

Figure 1. Mean percentage of correct responses by age for each of the seven tasks in Study 1.

$F(2, 38) = 8.87$, $p < .001$, $\eta^2 = .32$, and a three-way interaction among age group, intention, and outcome, $F(2, 38) = 7.84$, $p < .001$, $\eta^2 = .29$.

The three-way interaction was decomposed by examining the effects of the groups' judgments of teaching and imitation for each of the outcomes separately. When the successful outcome of learning was present, the 3- and 5-year-olds differed in their judgments of teaching and imitation as shown by a significant interaction between group and intention, $F(1, 39) = 8.86$, $p < .005$, $\eta^2 = .18$. The 3-year-olds did not show evidence of distinguishing between the stories on the basis of intent. When learning occurred, they said that one character tried to teach the other in both the teaching and the imitation stories. As a consequence, the 3-year-olds were more often correct on the teaching than imitation stories, $t(20) = 4.08$, $p < .001$ (two-tailed), $d = .43$. The 5-year-olds, in contrast, judged according to intention. They said that the character was trying to teach in the teaching stories and was not trying to teach in the imitation stories.

There was not a similar interaction between group and intention for either the failed or the unknown outcome stories. Overall, the 3-year-olds still showed worse performance than the 5-year-olds on stories with these outcomes, $Fs(1, 39) = 16.48$ and 11.67, $p < .001$, $\eta^2\text{s} = .30$ and $.23$, for the failed and unknown outcomes, respectively. However, the lack of Group × Intention interactions for these two outcomes indicates that the 3-year-olds were not responding at a lower level on the imitation than the teaching stories for the failed and the unknown outcomes, as they had for the successful outcome. In summary, the three-way interaction indicated that when there was a change in knowledge, 3-year-olds appeared to judge that it must be the result of teaching, and therefore mistakenly said that the character tried to teach in the imitation stories. They were much less inclined to make this mistake when there was no knowledge change or when the outcome of the story was unknown. No effect of outcome was detected for the 5-year-olds. They were able to distinguish teaching and imitation at near-ceiling levels across all three outcomes.

The results for the false-belief task were consistent with what has been found previously with these age groups (Wellman, Cross, & Watson, 2001). The 3-year-olds showed a poorer understanding of false belief because they claimed that the character would search where the hidden object was rather than where it had originally been placed. The 5-year-olds were better at determining that the character would mistakenly search at the old location, $t(39) = 5.8$, $p < .001$ (two-tailed), $d = .59$.

Comparisons to chance. The comparisons to chance largely confirmed the preceding analyses. How many children in each age group succeeded on each task was compared to chance using the binomial sign test. The 3-year-olds' responses were above chance on the successful teaching, teaching with unknown outcome, failed imitation, and imitation with unknown outcome stories. These findings add information to the comparisons among the six intention–outcome tasks. They verify that the 3-year-olds did not give accurate answers to the successful imitation story and that they were able to judge both teaching and imitation correctly when the outcome was unknown. The new information was added for the failed outcome. Although the ANOVA did not detect a Group × Intention interaction for the failed outcome stories, the 3-year-olds were only above chance on the failed imitation stories and not on the failed teaching ones. This finding indicates that the 3-year-olds were not able to say correctly that the character tried to teach when the teaching was not successful.

When considered along with the chance performance on the successful imitation task, the failed teaching results may indicate that 3-year-olds assume that teaching must be successful before it can be concluded that someone tried to teach, in addition to thinking that a successful outcome of learning is enough to say the cause was teaching.

The comparisons to chance were in agreement with the findings of the group differences for the false-belief tasks. The 3-year-olds were not above chance on false-belief indicating that they did not recognize that another would have a mistaken belief about the location of an object. The 5-year-olds' responses were above chance on all the stories.

Individual patterns of responding. The response patterns for the individual children were examined to see if they reflected the group differences. Children were given credit for passing the teaching or imitation stories if they answered at least five of the six of each. Nineteen of the 5-year-olds were successful on the teaching and imitation tasks, whereas only 7 of the 3-year-olds were, $\chi^2(1, N = 41) = 14.24$, $p < .001$. Of the 14 unsuccessful 3-year-olds, 8 passed the teaching tasks but not the imitation ones, 1 did the reverse, and the rest failed both. The individual patterns of responding verify the age differences found on the tasks and suggest that the teaching tasks as a group may have been slightly easier than the imitation ones.

Relations among the tasks. The zero-order Pearson correlations among the tasks for the 3-year-olds are shown in Table 1. Similar correlations were not computed for the 5-year-olds because their near-ceiling

Table 1

Simple Correlations Among Age and the Seven Tasks for the 3-Year-Olds in Study 1

Variable	1	2	3	4	5	6	7	8
1. Age (in months)	—	.06	−.10	−.36	−.06	.00	.12	.48*
2. Successful teaching		—	.49*	.44*	−.26	−.16	−.10	.00
3. Failed teaching			—	.62**	−.12	−.07	−.21	−.06
4. Unknown outcome teaching				—	−.03	−.16	−.35	.05
5. Successful imitation					—	.60**	.59**	.48*
6. Failed imitation						—	.72***	.08
7. Unknown outcome imitation							—	.32
8. Location false belief								—

$^{*}p < .05$ (two-tailed). $^{**}p < .01$ (two-tailed). $^{***}p < .001$ (two-tailed).

performance produced a lack of variance on many of the items.

The 3-year-olds' responses on the three teaching tasks were positively correlated with each other, $r(21) > .44$, $p < .05$, but not with anything else. Because this pattern indicates that children who answered one of the teaching tasks correctly tended to answer the other teaching ones correctly, it suggests that the subset of 3-year-olds who were successful may have been using intention to judge because the outcomes differed across the tasks. Responses on the three imitation tasks were similarly intercorrelated, $r(21) > .59$, $p < .01$. This pattern may have the similar implication that some of the 3-year-olds were using the common feature of a lack of intention to give a consistent answer across the three different outcomes. Passing the false-belief task was only related to correct judgments on the successful imitation stories, $r(21) = .48$, $p < .05$. Table 2 shows that the same correlations remained after age was partialled.

Discussion

Children's understanding of teaching shifted between 3 and 5 years, as reflected in a growing ability to distinguish teaching and imitation across different outcomes. Five-year-olds provided correct judgments across all the tasks. Three-year-olds did not distinguish between teaching and imitation for successful learning and were more influenced by outcome in general. Three-year-olds' responses were correlated within the teaching and within the imitation tasks. Their performance on the successful imitation task was related to their judgments on the standard false-belief task.

The comparison of teaching and imitation was employed in the study to test children's sensitivity to intention in judgments of teaching. Five-year-olds successfully stated that "trying to teach" occurred for teaching and not for imitation across all three outcomes—knowledge change, no knowledge change, and no information about outcome. In contrast, 3-year-olds did not separate successful teaching and successful imitation. They correctly judged successful teaching as teaching but also mistakenly regarded successful imitation as teaching. The 3-year-olds' similar judgments on the successful teaching and successful imitation stories indicate that they were using outcome to judge, and that they expected the positive outcome to have been brought about by an intentional action.

Table 2

Age-Partialed Correlations Among the Seven Tasks for the 3-Year-Olds in Study 1

Variable	1	2	3	4	5	6	7
1. Successful teaching	—	.49*	.50*	−.26	−.15	−.11	−.03
2. Failed teaching		—	.63**	−.13	−.07	−.20	.02
3. Unknown outcome teaching			—	−.06	−.16	−.34	.27
4. Successful imitation				—	.60**	.60**	.59**
5. Failed imitation					—	.72***	.09
6. Unknown outcome imitation						—	.32
7. Location false belief							—

$^{*}p < .05$ (two-tailed). $^{**}p < .01$ (two-tailed). $^{***}p < .001$ (two-tailed).

These results are similar to what Astington and Lee (1991) discovered in their study of intentional and accidental actions. They found in their example stories about birds eating breadcrumbs that young children judged that the birds could not have received the breadcrumbs by accident but had to have been given them. A similar result occurred here because the 3-year-olds judged that, when a knowledgeable person was present, the successful outcome of learning must have occurred through teaching. They did not base their judgments on intention and consequently considered imitation to be teaching. The 5-year-olds, on the other hand, realized that successful outcomes come about in different ways, through accidents or from the student's own learning, and therefore were able to differentiate the nonintentional instance of imitation (nonintentional on the knowledgeable person's part) from the intentional one of teaching.

It is interesting that the only correlation that the theory of mind task of false belief showed in the study was with the successful imitation story. Three-year-olds perform poorly on false belief because they typically make reality errors (Wimmer & Perner, 1983). The reality error in the change-of-location false-belief task is to predict that the character will look where the chocolate actually is rather than where the character originally put it. In other words, the error is to predict a successful outcome. The 3-year-olds in the current study may have shown a related response on the successful imitation task because the error on it was to assume, given a successful outcome, that an intentional act must have been responsible. This pattern is consistent with the view that 3-year-olds' understanding of theory of mind is limited by the reasoning that they can apply to intentional action (Frye, 1999). The overemphasis on a positive outcome could prevent young children from seeing how a false belief will affect someone's action and also prevent them from distinguishing between successful imitation and successful teaching.

Performance on the other tasks in the intention–outcome set was in accord with the interpretation that the 3-year-olds expected a successful outcome to be linked with the intentional act of teaching. The results of the failed teaching task fit that pattern. The 3-year-olds did not score above chance in recognizing that these stories described an attempt to teach. Compared to the successful teaching stories, the lack of a successful outcome reduced their ability to determine that the first child had tried to teach. The result demonstrates that along with assuming that a successful outcome implies teaching, 3-year-olds also seem to assume that teaching implies a successful outcome.

In contrast to young children's difficulty in judging successful imitation and failed teaching, the 3-year-olds made reasonably accurate judgments concerning situations in which no information was provided about the outcome. Their performance was at similar levels to the 5-year-olds. When the outcome was not stated, children could not use it in their judgments and could only rely on the information regarding the agent's intention. The results show that the 3-year-olds were able to use intention when it was presented this way. They performed at a level higher than chance on both the imitation and the teaching unknown-outcome stories, indicating their ability to distinguish between the two activities in situations that require consideration only of intention. Intentional teaching with no information about the output was thus judged as trying to teach, whereas imitation with no such information was not labeled teaching.

The pattern of results for all six intention–outcome tasks indicated that the more the teaching outcomes differed from success, the worse the 3-year-olds' responses were. On the other hand, the more the imitation outcomes differed from success, the better the 3-year-olds were. With regard to 3-year-olds' understanding of intention, the pattern fits a matching strategy (Astington, 1991; Schult, 2002; Shultz & Wells, 1985) and adds more information about it. The successful imitation task indicates a matching strategy because the successful outcome of learning led the 3-year-olds to the incorrect assumption that it must have been brought about by the intentional activity of teaching. The failed teaching task extends the idea of a matching strategy, but one in reverse, because when there was an unsuccessful outcome it led the 3-year-olds to the incorrect assumption that teaching had not even been attempted. However, the 3-year-olds' performance was not entirely defined by matching. When the strategy could not be used because the outcome was unknown, 3-year-olds employed the intention information in isolation to distinguish teaching and imitation. The 5-year-olds, in contrast, were not misled by outcome in any instance. They were able to use intention throughout to judge when there was an attempt to teach.

Study 2

Although the previous study found a preschool change in the use of intention to understand teaching, the timing of the improvement was difficult to determine because 3-year-olds were only compared to 5-year-olds. The current study attempted to examine the change more closely by comparing 3-, 4-, and

5-year-olds. The previous study also found that a successful outcome of knowledge change seemed to influence the 3-year-olds the most, leading them to misidentify imitation as teaching. To test this possibility further, a new task was introduced in which a partial change in knowledge was presented. If any change in skill or knowledge is sufficient to influence 3-year-olds, then the partial condition should produce a lack of discrimination between imitation and teaching again. In contrast, if it is the accomplishment of the full goal of acquiring the new skill or knowledge that is important, then the partial outcome should behave more like the failed one and permit the recognition of imitation.

Two new comparisons were included to explore how the recognition of intention is needed to understand instructional activities. In guided discovery learning (Mayer, 2004), teaching can be presented as a game in which play or exploration leads to a new skill or insight. For example, a teacher might have children play a card game in order to have them learn to recognize numbers. The intentional definition of teaching would classify this activity as teaching because of the goal involved. If there is a preschool change in understanding the intentional aspects of instruction, it could allow children to recognize the activity to be teaching rather than just play.

Intention may have similar importance in more specific instructional interactions in which knowledge is being exchanged. For instance, teachers often ask students questions, not because the teacher does not know the answer but because they want to find out if the student knows. Understanding the question's instructional significance, why it is being asked, requires understanding the underlying intent. Thus, both of these acts—instructional play and question asking—have ulterior motives that must be recognized to understand the real nature of the activity.

Finally, two new theory of mind tasks were incorporated. False belief was the only standard theory of mind assessment in the previous study. To assess the development of the understanding of intention as well, two judgment-of-intention tasks from Schult (2002) who found changes over this period were presented. The first task, intention unfulfilled/desire satisfied, involved stories in which an intentional action failed yet the desired outcome still occurred. Performance on this task might be related to understanding successful imitation because it also describes a successful outcome that had a different cause. The second type, intention fulfilled/desire unsatisfied, presented stories in which an action was carried out but, because of another event, did not result in the desired outcome. Performance on these stories might be related to understanding failed teaching because it also involves carrying out an appropriate action that does not succeed.

Method

Participants. Seventy-five children from six preschools in Israel participated. There were twenty-five 3-year-olds (10 boys and 15 girls, $M = 43.04$ months, range = 39–47 months), twenty-five 4-year-olds (13 boys and 12 girls, $M = 51.96$ months, range = 48–59 months), and twenty-five 5-year-olds (6 boys and 19 girls, $M = 66.64$ months, range = 60–75 months). The children were proficient in Hebrew and primarily from middle-class families. None of the families were new immigrants; over 85% of the parents were born in Israel.

Design. There were 11 types of stories, 6 of which were new. An example of each of the new types is given in the Appendix. The new types were as follows partial knowledge change teaching, partial knowledge change imitation, hidden intention game, hidden intention question, and two judgment-of-intention tasks from Schult (2002).

The set of teaching-related stories which presented different pairings between the agent's intention and its outcome was altered from the prior study by substituting the new partial knowledge change stories for the previous unknown outcome ones. The partial knowledge ones were added to test if it was successful knowledge change that affected young children's judgments. With the new stories, there were still six of these types, formed by the agent's act either reflecting an intention to teach or not (teaching vs. imitation) and the outcome taking the forms of successful knowledge change, partial knowledge change, or no change. The word *learning* was also removed from the teaching stories so that they closely matched the imitation ones.

The hidden intention game task tested whether teaching could be recognized despite being a part of another activity. In these stories, the agent has the intention to teach, but the instructional activity was embedded in a game. Children were asked whether the agent was using the activity to play or to teach. Another task tested whether children can understand that questions can be used for assessing knowledge rather than seeking information. Children had to say whether a question was being asked because a person who had been teaching wanted to know the answer or wanted to find out what the student knew.

Children's theory of mind understanding of intentional action outside of the realm of teaching was examined with two types of tasks from Schult (2002). Intention-unfulfilled/desire-satisfied and intention-fulfilled/desire-unsatisfied stories were presented because they exhibited age-related changes in Schult's original study and might correspond to successful imitation and failed teaching, respectively. Wording of the stories was not changed, except that only the intention test question was presented, and it was stated in terms of "try to or did not try to" in order to match the test question of the teaching stories. The other theory of mind development of false-belief understanding was again assessed using the same change-of-location format as before.

Procedure. As in the previous study, children were presented with 2 stories in each of the 11 types for a total of 22 stories per child across two sessions separated by about a week. One story of each type was given per session. For the six teaching and imitation tasks, one story of each type described the agent performing an academic skill and the other described a nonacademic skill. Presentation order of the academic and nonacademic skills was counterbalanced across the participants. The stories were read in Hebrew and enacted as in Study 1. Two versions of the intention-unfulfilled/desire-satisfied and intention-fulfilled/desire-unsatisfied tasks were presented as in Schult (2002). The standard change-of-location false-belief task (Wimmer & Perner, 1983) was again presented twice with different materials and characters.

As before, control and test questions were in forced-choice format with the order of the two choices counterbalanced for each participant.

Results

Scoring. Choosing the try-to-teach answer in response to the test question was counted as correct for the successful, partial, and failed outcome teaching stories. The did-not-try-to-teach answer was accepted as correct for the successful, partial, and failed outcome imitation stories. The really-wants-to-teach and wants-to-see-what-student-can-do replies were correct for the hidden intention game and question stories. The did-not-try-to response was correct for intention-unfulfilled/desire-satisfied stories and the did-try-to response was correct for the intention-fulfilled/desire-unsatisfied ones. Prediction of search in the original place was correct in the change-of-location false-belief task.

McNemar tests were again employed to compare the two story versions in each task type. The only difference found was for the intention-fulfilled/desire-unsatisfied stories, McNemar's $\chi^2(1, N = 75) = 8.05, p = .007$. Children were more successful on the story about shoes compared to the one about a snack. A similar difference was not found in Schult (2002). Because it is not clear if this difference is reliable or has theoretical significance, responses for this task were nonetheless combined, in line with those across the other tasks, yielding scores that ranged from 0 to 2 for each task type.

Age and task differences. The mean percentages of correct responses for the three age groups on each of the eight teaching, imitation, and hidden intention tasks are shown in Figure 2. The six intention–outcome tasks were again analyzed together because they followed a factorial design comparing the intentional (teaching) and nonintentional (imitation) situations for the three outcomes of successful, partial, and failed learning. Because gender did not have an effect, answers to the test question were analyzed in a 3 (age) × 2 (intention) × 3 (outcome) MANOVA. There was a main effect of age group, $F(2, 72) = 30.33, p < .001, \eta^2 = .46$, with success increasing with each age. There was also a two-way interaction between intention and outcome, $F(2, 71) = 57.92, p < .001, \eta^2 = .62$, and a three-way interaction among group, intention, and outcome, $F(4, 142) = 10.27, p < .001, \eta^2 = .22$.

The three-way interaction was decomposed by examining the effects of the groups' judgments of teaching and imitation for each of the outcomes separately. Significant interactions between group and intention were found for all three outcomes, $Fs(2, 72) = 15.41, 6.01$, and $5.40, p < .01, \eta^2s = .30, .14$, and $.13$, for successful, partial, and failed outcomes, respectively. To interpret these two-way interactions, the effect of group was tested for each intention separately at each of the outcomes.

With the successful outcome, there was an age difference for imitation, $F(2, 72) = 17.95, p < .005, \eta^2 = .33$, but not for teaching. Bonferroni comparisons showed better performance for the 5-year-olds than the other two groups on successful imitation. The pattern for intention was reversed for the other outcomes. There was an effect of age on partial and failed teaching, $Fs(2, 72) = 16.71$ and $16.48, p < .001, \eta^2s = .32$ and $.31$, but not on partial or failed imitation. All three age groups were different from each other for partial teaching. For failed teaching, the 5-year-olds performed better than the other two groups.

In sum, the pattern for the three-way interaction repeated and expanded what was found in Study 1. When there was a successful outcome, judging imitation was difficult for the 3- and 4-year-olds because they misidentified successful imitation to be teaching. In contrast, when there was a failed outcome, judging teaching was a problem for the 3- and 4-year-olds

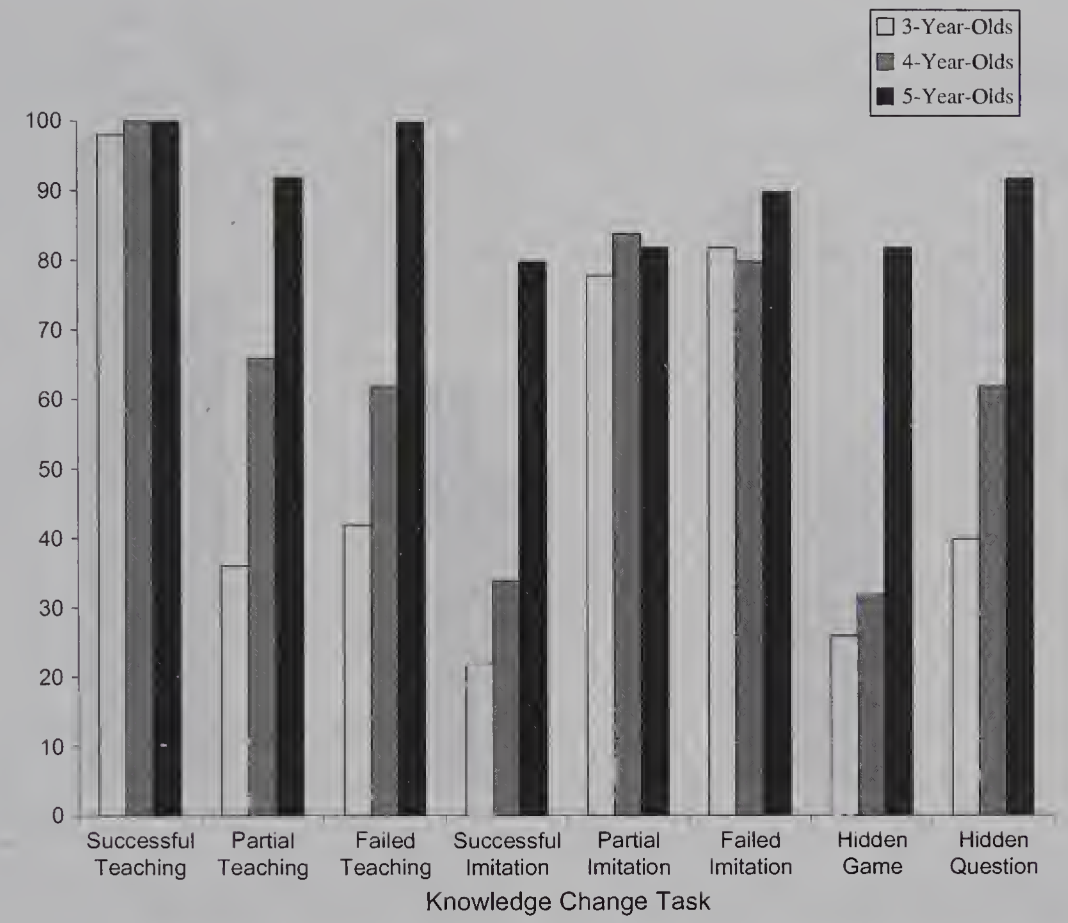

Figure 2. Mean percentage of correct responses by age for each of the eight knowledge change tasks in Study 2.

because they tended to say there had not been an attempt to teach. The new finding was that the pattern for the partial outcome resembled the failed one. The two younger groups realized that there had been no attempt to teach with partial imitation, but they also incorrectly said that there had been no attempt to teach when teaching resulted in a partial outcome.

The hidden intention game and question tasks were analyzed in a 3 (age) × 2 (task) MANOVA. Main effects were found for age, $F(2, 72) = 30.43$, $p < .001$, $\eta^2 = .46$, and task, $F(1, 72) = 9.58$, $p < .01$, $\eta^2 = .12$. Bonferroni comparisons showed that the 5-year-olds performed better than both the 3- and 4-year-olds. In addition, response levels on the question stories were higher than on the game stories. Overall, children were better at recognizing that when a teacher asks a question in these stories, the intent is to see whether the learner knows the answer than they were at understanding that when teacher plays a game with the learner the intent is to teach.

The mean percentages of correct responses for the three age groups on the false-belief, intention-unfulfilled/desire-satisfied, and intention-fulfilled/desire-unsatisfied tasks are shown in Figure 3. These responses were analyzed together because they examined different standard aspects of theory of mind. A 3 (age) × 3 (task) MANOVA found main effects for age, $F(2, 72) = 47.23$, $p < .001$, $\eta^2 = .57$, and task, $F(2, 71) = 11.78$, $p < .001$, $\eta^2 = .25$. Bonferroni comparisons revealed each of the groups improved with age, and the intention-fulfilled/desire-unsatisfied task was easier than the other two.

Comparisons to chance. For the teaching and imitation tasks, the comparisons to chance largely confirmed the preceding analyses and showed similarities between 3- and 4-year-olds' performance. Both age groups were above chance on successful teaching, partial imitation, and failed imitation. In addition, the 3-year-olds were below chance on successful imitation. These findings verify that the 3- and 4-year-olds did not give accurate answers to the successful imitation story and that they were able to judge imitation, but not teaching, correctly when the outcome was partial or failed learning. The pattern strengthens the findings of Study 1 in indicating that 3- and 4-year-olds assume that teaching must be successful before it can be concluded that someone tried to teach, in addition to thinking that a successful outcome is enough to say the cause was teaching. The 5-year-olds' responses were above chance on all six of these tasks, showing that they were able to distinguish teaching and imitation on the basis of intention regardless of outcome.

The comparisons to chance for the two hidden intention tasks followed the MANOVA results. The

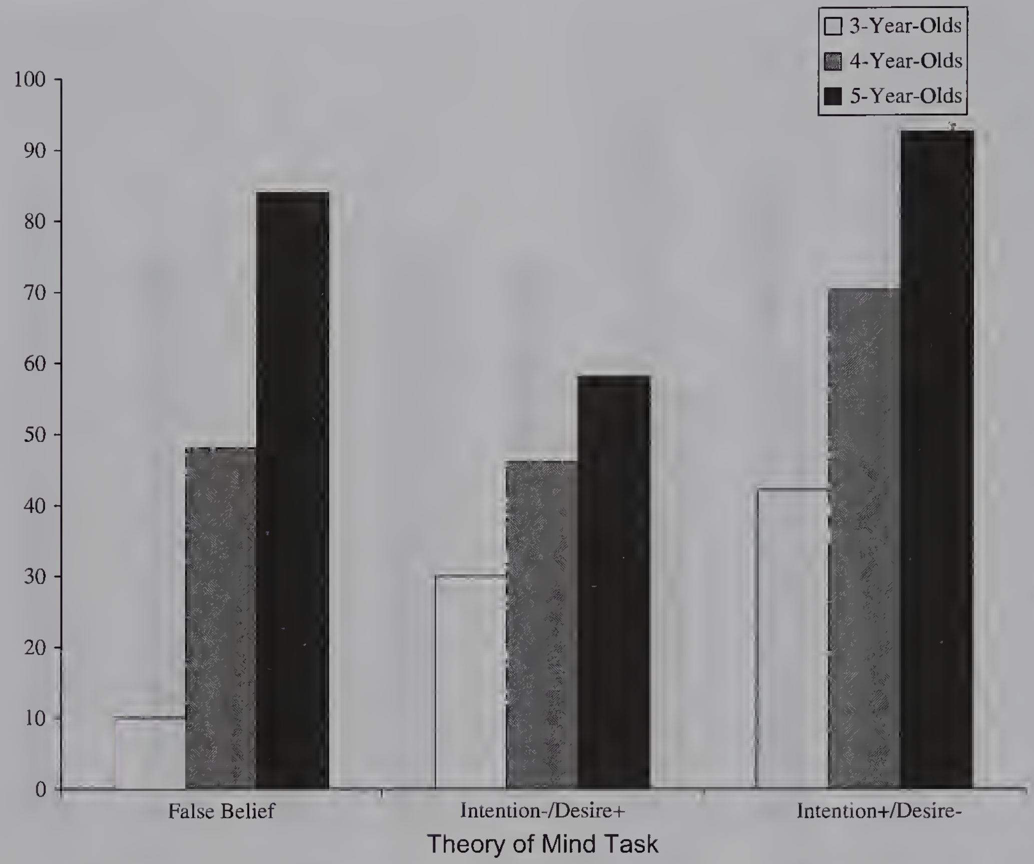

Figure 3. Mean percentage of correct responses by age for each of the three theory of mind tasks in Study 2.

3- and 4-year-olds' responses were not different from chance on either task, indicating that they did not recognize the instructional intention of playing the game or asking questions. The 5-year-olds' performance was above chance for both.

On the theory of mind tasks, the 3-year-olds' performance was below chance on false belief. Otherwise, the 3- and 4-year-olds' responses were not different from chance for either false belief or the two intention tasks. The 5-year-olds gave correct answers at above chance rates for false belief and the intention-fulfilled/desire-unsatisfied tasks, but not for the intention-unfulfilled/desire-satisfied one. Thus, even 5-year-olds had difficulty in recognizing that the satisfactory outcome in these stories was not a result of an intentional action.

Individual patterns of responding. The individual response patterns for the teaching and imitation stories were scored as in the previous study, with a minimum of five of the six stories correct needed to pass each. With the new hidden intention tasks, at least three of the four game and question stories had to be correct to pass these tasks. Using these criteria, there was one 3-year-old, three 4-year-olds, and seventeen 5-year-olds who passed the teaching, imitation, and hidden intention tasks, revealing a strong difference in the number of children who succeeded with age, $\chi^2(2, N = 75) = 30.16, p < .001$.

Of the children who did not pass all the tasks, the pattern was clear for the 5-year-olds. Of the 7 children who did not pass all the tasks, 3 passed the teaching and imitation tasks but not the hidden intention ones and 4 passed only the teaching and hidden intention ones. These were the same categories as in Study 1. The most frequent patterns overlapped for the 4-year-olds: Of the 21 children who did not pass all the tasks, 4 passed the teaching and imitation, 5 passed teaching and hidden intention, 4 passed the teaching alone, 2 passed imitation alone, and 6 did not pass any of the three. There were three patterns that were common for the 3-year-olds. Of the 24 children who did not pass all the three types, 6 only succeeded on imitation, 5 only on teaching, and 13 did not pass any of them. The individual patterns of responding show again that it was only the 5-year-olds who appeared to succeed across all the knowledge change tasks.

Relations among the tasks. The zero-order Pearson correlations and age-partialed correlations among the tasks for the 3-, 4-, and 5-year-olds are shown in Tables 3 and 4. Many of the correlations remained even after age had been partialed. The age-partialed correlations revealed separate patterns for teaching and imitation. Successful teaching was only negatively correlated with successful imitation. However, partial and failed teaching was related to each other. The imitation tasks also shared similar responding.

12. Intention+/Desire−												—

*$p < .05$ (two-tailed). **$p < .01$ (two-tailed). ***$p < .001$ (two-tailed).

All three were related to each other. In addition, the partial and failed teaching tasks were negatively related to the partial and failed imitation ones. These patterns are similar to Study 1 in showing that teaching and imitation tended to form two distinct sets of tasks and here responding was negatively related across the sets.

The only correlation for the hidden intention tasks was that the question task was related to failed teaching. Among the standard theory of mind tasks, false belief was again only related to successful imitation. This outcome replicates what was found in Study 1 and adds substantial support for this specific relation. With the intention tasks, intention fulfilled/desire unsatisfied was related to partial and failed teaching. This relation is plausible because in all three tasks, the actor carries out the action but does not succeed in bringing about the outcome.

Discussion

The current results support the age difference in the understanding of teaching found in the previous study. The 3-year-olds again appeared to incorporate outcome in their conception of teaching. When there was a successful outcome, they identified imitation as teaching, despite the lack of intention on the model's part. When there was no learning in the failed teaching story, they judged that there had not been an attempt to teach. The three age groups allowed for a better assessment of the timing of the change in the understanding of teaching. In general, the results for the 4-year-olds were closer to those of the 3-year-olds rather than the 5-year-olds, putting the change between 4 and 5 years. The new partial teaching and imitation situations showed that the young children only counted full learning as success. When just

several letters of a word were learned or a face partially drawn, the 3-year-olds' responses corresponded to those of the failed stories in stating that there had not been an attempt to teach. This finding indicates that any change in knowledge or skill was not enough to affirm an attempt to teach. The outcome appeared to have to fulfill the goal of the teaching before the young children acknowledged that there was an attempt to teach.

The other tasks exhibited similar age patterns to the teaching–imitation ones. The 5-year-olds performed better than the other two groups on the hidden intention tasks about the real point of the game or the teacher's question. Performance overall was slightly better on the question task, suggesting that perhaps children are more accustomed to interpreting the hidden intent of teacher's questions. The age differences for the theory of mind tasks were also similar. Only the 5-year-olds succeeded on false belief. Success on the judgment-of-intention tasks also showed a change over this age period, as Schult (2002) found, although the intention-unfulfilled/desire-satisfied stories were difficult even for the 5-year-olds. Similar to the teaching and imitation stories, these tasks can be viewed as presenting a disparity between intention and outcome, and 3-year-olds seem to display their characteristic pattern of responding. In the intention-fulfilled/desire-unsatisfied task, in which an intentional action was not successful, the 3-year-olds incorrectly judged that the person had not tried to bring about the outcome. In the intention-unfulfilled/desire-satisfied one, in which the successful outcome did not depend on the person's action, 3-year-olds, and many of the older children, incorrectly said that the person tried to produce the outcome. Both of these tasks again show the influence of a successful outcome on young children's judgments.

The age-partialed correlations reaffirm the links found before. Responding was related on the partial and failed teaching tasks and among the imitation tasks, although it was dissimilar across these two sets. The specific relation between understanding of false belief and successful imitation was again found. The replication of this correlation with a new sample and wider age range suggests that it is a reliable finding. It was proposed before that the two judgments might be connected because they could both require the understanding that in some instances success cannot be the sole consideration. In other words, young children who fail these tasks mistakenly make the simplest assumptions that searching will produce the hidden object and learning is brought about by teaching. By this logic, the intention-unfulfilled/desire-satisfied task should have also been related, although the overall difficulty of this task may indicate that there is more involved in it. A relation was found between the intention-fulfilled/desired-unsatisfied task and the partial and failed teaching ones. This relation is interpretable in intention–outcome terms in that all three represent instances in which the appropriate action was accomplished but a successful outcome did not follow.

General Discussion

The overall results of the two studies provide evidence of a change in preschoolers' understanding of the intentional aspect of instruction. Three- and 4-year-olds frequently judged by outcome. When there was successful learning, they judged there had been an attempt to teach, even in the case of imitation. When teaching failed, they did not say that there had been an attempt to teach. It was only when the outcome was unknown in Study 1 that they seemed to be able to use intention to identify teaching and imitation. The 5-year-olds' sensitivity to intention allowed them to distinguish teaching and imitation, recognize teaching even when it was not successful, and see the hidden instructional intent of games and questions despite their surface appearance. These findings show that recognition of intention is crucial for comprehending the common knowledge acquisition process represented by teaching and that children's understanding of teaching changes significantly over the preschool period.

The change makes a difference for the characteristics of the children's concept of teaching. Except for their performance when an outcome was unknown, the 3-year-olds had close to a functional definition of teaching. Because the functional definition relies on a successful outcome to designate teaching, it does not separate successful teaching from successful imitation or identify failed teaching as an attempt to teach. The 5-year-olds' use of intention gave them a different conceptual basis for interpreting teaching. Because they were able to consider intention, they could distinguish successful teaching and successful imitation on the basis of whether the actor was trying to change the knowledge state of the observer or not. Similarly, they were able to continue to identify failed teaching as an attempt to teach because they understood what the actor was trying to do, despite not succeeding.

Understanding an underlying intention also makes it possible to recognize instructional characteristics that are not obvious. The older preschoolers began to see that a game in the classroom could actually be an instance of instruction (i.e., guided discovery learning) because it fit with what the teacher was trying to accomplish. Seeing the intention allows a new insight into activities, such that understanding what the activity is used for rather than what it is becomes more important. Understanding the point of questions showed a similar change. There are several ways preschoolers could perceive adult questions (Donaldson, 1978). The current findings suggest that young preschoolers still see them as simple requests for information, but that 5-year-olds can recognize when they are being used to assess the child's knowledge.

Children's growing understanding of games and questions that can be embedded in teaching suggests that they gradually come to understand the *process* of teaching and the means teachers use to accomplish their goals. Recognizing the meaning of questions for teaching at the age of 5 years is especially important because it shows an awareness of the teacher's focus on the change in learners' knowledge and the need to continuously assess and respond to learners' understanding. Whereas recognition of teachers' intention—to enhance learner's knowledge or understanding based on identifying a knowledge gap between learner and teacher (Ziv & Frye, 2004)—give the necessary conditions for initiating teaching and for identifying teaching situations, understanding the meaning of teaching activities reflects an appreciation of the dynamics of teaching.

Fully understanding the dynamic aspects of selecting appropriate instructional tactics and modifying them on the basis of learners' responses to an instruction may require second order theory of mind reasoning (Wood et al., 1995). For instance, higher order, recursive reasoning is important for recognizing learners' failure to understand what a teacher tried to teach (e.g., teacher thought that X would understand that she meant him to know or do) and modification of subsequent instruction in light of this recognition. Five-year-olds' understanding of teacher's use of questions may indicate an initial appreciation of teachers' responses to learners' needs. An increased understanding would be expected between ages 5 and 7, as children improve in their understanding of the recursive nature of mental states (Perner, 1988; Perner & Wimmer, 1985).

The current results suggest that teaching should be considered among other common forms of knowledge acquisition—perceptual access, inference, communication and testimony, and learning—studied within theory of mind. It will be important to determine how children understand each of these different interactions. The present study gives an example of how the understanding of two of the forms are related in that recognizing the presence or absence of intention allowed teaching and imitation to be discriminated. Examining the mental states involved can also distinguish these forms from other theory of mind effects. For instance, teaching is different from deception, which has long been studied in theory of mind (Wimmer & Perner, 1983), not because one is intentional and the other is not, but because the intent in one is to increase knowledge and the intent in the other is to distort it. It may be that all these forms of knowledge change belong to a related family of effects that could be better understood by exploring the differences and similarities among them.

Research on children's understanding of the relation between teaching and learning seems to be the most natural next step. A central question concerns children's conceptions of the similarities and differences between the two activities. Using intention to analyze teaching draws an important distinction between teaching and learning. According to the current approach, teaching must be intentional, but the same is not true for learning. Although much of our learning is intentional, for learning to occur there merely has to be a change in the person's knowledge or understanding, regardless of the experience that caused the change (Frye & Ziv, 2005). Exploring children's understanding of the correspondence between teaching and learning will portray a richer picture of their developing understanding of knowledge acquisition processes.

The findings concerning preschoolers' understanding of teaching may also open new questions about how young children perceive the actual teaching and learning situations that they encounter everyday in preschool and perhaps at home. For instance, because 3-year-olds strongly rely on outcome, when successful learning occurs in the presence of an adult it may be perceived as teaching, even though there was no act or intention on the adult's part. Thus, 3-year-olds could perceive spontaneous or imitative learning that occurs at school and home as being caused by the adult, rather than by the learner's practice or intentional attempts to master a new skill. Certainly, when young children are asked how they learned to do something so well (e.g., put together a puzzle), they often say that their teacher, parents, or siblings taught them.

The high percentage of 3-year-olds who do not acknowledge failed teaching as an attempt to teach further emphasizes young children's strong reliance on a successful outcome in conceptualizing teaching. Their assumption seems to be that teaching always brings about learning, otherwise it is not teaching.

This view raises an interesting question of when no learning occurs, and yet "teaching" acts may have been observed by young children, how do they interpret them? When a teacher shows a child how to assemble a new toy or how to play a new game and the child does not understand, is the teacher's activity regarded as some kind of a routine communication or a common attempt to play? If young children do not appreciate what unsuccessful teaching is, it strongly suggests that they will not see the point of what the teacher was attempting to do.

Although young children's understanding of teaching is restricted compared to the understanding of older children and adults, it provides the conceptual foundations for the shift in understanding that occurs between the ages 3 and 5 years and for understanding teaching situations that are likely to be common in preschools. The 3-year-olds in the current study showed an understanding of the causal relation between teaching and learning when the outcome was successful. Furthermore, they correctly identified situations that depicted an attempt to teach when no information was given about the outcome. Children may often observe a teacher teaching a child and not know the outcome. Three-year-olds may assume a successful outcome in these situations and therefore be able to account for them as teaching, but doing so could also help them to see the teachers' acts of demonstrating, showing, and explaining as being relevant to teaching. In that case, the experiences would allow young children to learn about aspects of teaching in more instances than just when it results in obvious learning.

An additional important question of the current findings concerns the effects that understanding teaching as a form of knowledge acquisition might have for the child's own learning. Within theory of mind research, it has been shown that understanding perceptual access grants children an advantage in choosing what information to accept (Povinelli & deBlois, 1992). In fact, there is evidence that preschoolers make generalized judgments about whether a person's knowledge is trustworthy (Koenig & Harris, 2005). It has been established as well that improvements in theory of mind are related to observable changes in children's own ability to teach (Davis-Unger, 2008; Strauss et al., 2002). It is also possible that changes in the understanding of teaching make a difference for the child's ability to learn from it. There are already some positive indications of this possibility because older preschoolers learn more when they are told that they are going to be taught (Jeffrey, 2003; Taylor, Esbensen, & Bennett, 1994) and when teachers appear certain about their own knowledge (Sabbagh & Baldwin, 2001). In exploring this issue, it will also be important to consider individual differences in children's understanding of teaching and how they benefit from different learning situations.

The changes in children's understanding of teaching that are evident by 5 years may have important educational implications for formal instruction. Because 5-year-olds appear to realize that teaching is intentional, they can distinguish teaching from imitation, identify teaching despite a negative outcome, and recognize it even when it is embedded in a different activity. The first educational implication of these theory of mind changes is that they may contribute to the prerequisites that make children ready for formal instruction (Astington & Pelletier, 2005; Ziv & Frye, 2004). The conventional notion of school readiness emphasizes children's cognitive ability and their specific skills in literacy, numeracy, and social understanding. In addition, the current study suggests that 5-year-olds achieve a better understanding of the *process* that underlies most of the formal schooling experience, namely, teaching. Consequently, they should be in a better position to realize what schooling is about or, in other words, understand its basic intent and be able to take an active part in direct instruction.

Appendix

Protocols for Stories in Study 1

Successful teaching. Here are Itamar and Esti. Esti does not know how to make a bowl from clay. Itamar knows how to make a bowl from clay. Every day Itamar shows Esti how to make a bowl from clay, so that he learns how to do it. "Look, first you role the clay to a ball, then you stick your thumb into the ball, there, you have a bowl." Now Esti also knows how to make a bowl.

> Control Question 1: "At the beginning did Esti know how to make a bowl or didn't she know?"
> Control Question 2: "Does Esti know now how to make a bowl or doesn't she know how?"
> Test Question: "Did Itamar try to teach Esti how to make a bowl from clay or didn't he try to teach him?"

Successful imitation. Here are Uri and Dorit. Uri does not know how to tie his shoe laces. Dorit knows how to tie shoe laces. Every day Uri watches Dorit when she ties her shoe laces. (*Experimenter enacts Uri hiding behind Dorit.*) See, he sits here, behind the table, watches Dorit, and tries to do just what she does. Dorit does not see Uri. Dorit does not know that Uri is watching her. Look, now Uri knows how to tie his shoelaces.

> Control Question 1 (Perceptual Access Question): "Did Dorit know that Uri was watching her or didn't she know he was watching her?"
> Control Question 2: "At the beginning, did Uri know how to tie his shoelaces or didn't he know how?"
> Control Question 3: "Does Uri know now how to tie his shoelaces or doesn't he know how?"
> Test Question: "Did Dorit try to teach Uri how to tie his shoelaces or didn't he try to teach her?"

Failed teaching. Here are Gal and Ronit. Gal does not know how to play Animal Dominos. Ronit knows how to play Animal Dominos. Every day Ronit shows Gal how to play Animal Dominos, so that he learns how to play. "See, first you look for the same picture as here, and then you put the picture right next to this one. There, now you have two pictures that are the same right next to each other." Gal tried and tried to play, but he still does not know how to play. (*Experimenter enacts Gal putting pictures next to the wrong target picture.*)

> Control Question 1: "At the beginning did Gal know how to play Animal Dominos or didn't he know how to play?"
> Control Question 2: "Does Gal know now how to play Animal Dominos or doesn't he now know how?"
> Experimental Question: "Did Ronit try to teach Gal how to play Animal Dominos or didn't she try to teach him?"

Failed imitation. Here are Ofer and Galia. Ofer does not know how to jump on one leg. Galia knows how to jump on one leg. Every day Ofer watches Galia when she jumps on one leg, and he also tries to jump on one leg. See, he stands here, behind the door, watches Galia, and tries to do just what she does. Galia does not see Ofer. Galia does not know that Ofer is watching her. Ofer tries again and again to jump on one leg, but he still does not know how to do it. (*Experimenter enacts Ofer falling.*)

> Control Question 1 (Perceptual Access Question): "Did Galia know that Ofer was watching her or didn't she know he was watching her?"
> Control Question 2: "At the beginning did Ofer know how to jump on one foot or didn't he know how?"
> Control Question 3: "Does Ofer know now how to jump on one foot or doesn't he know how?"
> Test Question: "Did Galia try to teach Ofer how to jump on one foot or didn't she try to teach him?"

Unknown outcome of teaching. Here are Dan and Shani. Dan does not know how to write numbers. Shani knows how to write numbers. Every day Shani shows Dan how to write numbers, so that he learns how to write them. "See, this is how you write '1' and this is how you write '2'. Here are '1' and '2'."

> Control Question 1: "At the beginning did Dan know how to write numbers or didn't he know how to write them?"
> Test Question: "Did Shani try to teach Dan how to write numbers or didn't she try to teach him?"

Unknown outcome of imitation. Here are Dana and Amit. Dana does not know how to draw a house. Amit knows how to draw a house. Every day Dana watches Amit when he draws a house, and she also tries to draw a house. See, she sits here, behind the wall, watches Amit, and tries to do just what he does. Amit does not see Dana. Amit does not know that Dana is watching him.

> Control Question 1 (Perceptual Access Question): "Does Amit know that Dana is watching him or doesn't he know she is watching him?"
> Control Question 2: "At the beginning did Dana know how to draw a house or didn't he know how to draw a house?"
> Test Question: "Did Amit try to teach Dana how to draw a house or didn't he try to teach her?"

Standard false-belief stories. Here is Eyal and here is Tami. Eyal has a block. Eyal puts the block in the box and then he goes out to play. Now Eyal can't see and can't hear what Tami is doing. Tami takes the block out of the box and puts the block in the drawer instead.

> Control Question 1: "Where is the block now, is it in the box or is it in the drawer?"
> Control Question 2: "Where did Eyal put the block before going outside, did he put it in the box or did he put it in the drawer?"
> Test Question: "When he comes back, where will Eyal look for the block? Will he look in the box or will he look in the drawer?"

Protocols for New Stories in Study 2

Partial teaching. Here are Inbar and Oren. Oren wants to know how to write his name, but he doesn't know to write any letters. Inbar knows how to write. Look, here she's writing the names "Inbar" and "Oren." Every day Inbar shows Oren how to write his name, so that he knows how to write it. "Look, first you have to write the letter 'O' and then 'r', 'e', and then the letter 'n', like this." Oren tried to write his name but he can only write the two letters 'o' and 'r', like this.

> Control Question 1: "At the beginning did Oren know how to write his name or didn't he know how to write his name?"
> Control Question 2: "Does Oren know now how to write his name or doesn't he know how to write his name?"
> Control Question 3: "Does Oren know now to write some letters of his name or doesn't he know how to write some letters of his name?"
> Test Question: "Did Inbar try to teach Oren how to write his name or didn't she try to teach him?"

Partial imitation. Here are Roee and Yael. Yael wants to know how to draw a face of a man, but she doesn't know how to draw faces. Roee knows to draw a face. Every day Yael watches Roee drawing a face of a man. (*Experimenter enacts Yael hiding behind Roee.)* See, she sits here, behind the table, watches Yael, and tries to do just what he does. Roee does not see Yael. Roee does not know that Yael is watching him. Now Yael tries to draw a face of a man but she can only draw a circle with hair, like this.

> Control Question 1 (Perceptual Access Question): "Did Roee know that Yael was watching him or didn't he know she was watching him?"
> Control Question 2: "At the beginning did Yael know how to draw a face of a man or didn't she know how to draw a face of a man?"
> Control Question 3: "Does Yael know now how to draw a face of a man or doesn't she know how to draw a face of a man?"
> Control Question 4: "Does Yael know now to draw part of the face or doesn't she know how to draw part of a face of a man?"
> Test Question: "Did Roee try to teach Yael how to draw a face of a man or didn't he try to teach her?"

Hidden intention game. Here are Dan and Naomi. Dan wants to read numbers, but he doesn't know how to read numbers at all. Naomi knows how to read numbers. Look, here she is reading numbers 1, 2, 3, all the way to 10. Every day Naomi shows Dan how to read numbers, so that he knows how to read numbers too. "Look, this is number 1, this is 2, and this is number 3..." Today Naomi brings a game to class. Naomi says to Dan, "We are going to play the number game now. In this game every child gets a card and has to say what number appears on the card. The winner is the one who reads all the numbers.'' Now Naomi and Dan are playing the number game.

> Test Question: ''When the Naomi plays the number game with Dan, what does she really want? Does she want to play with the game with Dan or does she want to teach him numbers?''

Hidden intention question. Here are Tamar and Adam. Tamar wants to know names of shapes, but she doesn't know any name of any shape. Adam knows the names of all shapes. Look, here he's pointing at shapes and says, ''this is a square and this is a circle.'' Every day Adam shows Tamar shapes and he tells her what is the name of each shape, so that she knows its names too. ''Look, this is a triangle, and this is a circle.'' Now Adam shows Tamar a card with a shape drawn on it and asks her, ''What is drawn here?''

> Test Question: ''Why does Adam asks Tamar this question, because he wants to know what shape is drawn on the card or because he wants to see whether Tamar knows what shape is drawn on the card?''

Intention unfulfilled/desire satisfied (adapted from Schult, 2002). Here is Batya. Batya really likes playing with dolls. She would like a new doll to play with. There's a doll at the toy store that Batya wants. Batya has enough money to buy the doll. She decides she's going to the toy store to buy the doll. That day, before she went to the store, her mother gave her the doll. Now Batya has the doll.

> Control Question 1: ''At the beginning, did Batya have the doll or did she not have the doll?''
> Control Question 2: ''Does Batya have the doll now or does she not have the doll now?''
> Test Question: ''Did Batya try to go to the store and buy the doll or did she not try to go and buy the doll?''

Intention fulfilled/desire unsatisfied (adapted from Schult, 2002). Here is Gil. It's a rainy day and Gil has to walk home from school. He wants his shoes to stay dry, because he doesn't like having wet shoes. He decides he's going to walk around all the puddles. Gil walks very carefully and doesn't step into a single puddle. When he gets home, his shoes are still dry. Just then, his little brother spills water on is shoes.

> Control Question 1: ''At the beginning were Gil's shoes wet or dry?''
> Control Question 2: ''Now, are Gil's shoes wet or dry?''
> Test Question: ''Did Gil try to walk around the puddles to keep his shoes dry or did he not try to walk around the puddles to keep his shoes dry?''

Changes in the Relation of Self-Efficacy Beliefs and Behaviors Across Development

Pamela E. Davis-Kean, L. Rowell Huesmann, and Justin Jager

Indiana University

Jennifer E. Lansford
Duke University

Many social science theories that examine the connection between beliefs and behaviors assume that belief constructs will predict behaviors similarly across development. Converging research implies that this assumption may not be tenable across all ages or all belief constructs. Thus, to test this implication, the relation between behavior and beliefs about the self was examined in 2 independent data sets with 2 different constructs: aggression and achievement. The respondents were 6 – 18 years of age and predominately Caucasian. Results using quasi-simplex structural equation models suggest that self-beliefs become more strongly related to behavior as children grow older independent of the reliability of the measures used. Possible limitations in the use of self-report methodology with young children are discussed.

Children entering school are confronted with two important tasks: to achieve and to get along cooperatively with others. Because of the importance of these two tasks for positive development, many researchers have focused their research on trying to understand what might be the major influences on these outcomes. An important tenet of this work is that a link exists between beliefs about ability to perform a behavior (self-efficacy) and actually performing the behavior (e.g., Bandura, 1986; Crick & Dodge, 1994; Huesmann, 1988; Kohlberg, 1969; Wigfield & Eccles, 1992). The theoretical models based on these tenets are used to explain children's behaviors by the various belief domains that may be specific to the behavior. For example, when trying to understand achievement outcomes, children's beliefs about their ability to perform are often assessed and used to predict behavior (Bandura, 1986; Wigfield & Eccles, 1992). A similar method is used in research in which children's beliefs about appropriate behavior with peers are assessed in connection with their aggressive behaviors (Crick & Dodge, 1994; Huesmann & Guerra, 1997).

The models guiding this research imply that children's beliefs and expectations about their behavior will dictate or predict their behaviors and that this prediction is similar across development. Younger children, for example, would show similar relations between their beliefs about achievement and actual achievement as would older children. An assumption from these theories, then, is that a primary intervention for changing children's behaviors in achievement and peer relations is to change their beliefs about important behaviors and that the age of the child would not be a factor in this intervention. Even though these models linking beliefs and behaviors have been well examined across the years, the general focus has been on cross-sectional relations or short-term longitudinal studies with very limited age ranges (e.g., middle childhood or adolescence). This limitation primarily reflects the lack of longitudinal data that spanned from early schooling (e.g., first/second grade) to later schooling (high school). Thus, little research has examined the specific relation between self-beliefs and their associated behaviors across time.

This research was supported by the Center for the Analysis of Pathways from Childhood to Adulthood, which is funded by National Science Foundation Grant 0322356. We thank the following people for contributions of their data sets to this study: Kenneth A. Dodge and Gregory S. Pettit (Child Development Project), and Jacque Eccles, Alan Wigfield, Rene Harold, and Phyllis Blumenfeld (Childhood and Beyond Study). We are also very grateful for the statistical assistance of Chris Mutch, Jeremy Welland, Holly Sexton, and Jackson Goodnight.

A primary goal of this article is to examine the relation between self-efficacy beliefs and behaviors across time to determine the stability of this relation. A question of particular interest is whether this relation remains stable across time or changes as children age. A related question is whether, if the belief–behavior relation changes, the change is related to age. A second goal of this article is to examine these relations for two important developmental outcomes: achievement and negative peer relations (aggression). This type of research is important for understanding whether self-referent beliefs about behaviors are similarly predictive across time. If self-referent beliefs do not relate to behaviors similarly across time, then it is important to understand how these relations may change so that interventions may be appropriately targeted for the age of the child.

The Development of Beliefs and Behaviors

Considerable research has suggested that younger children have difficulties with certain tasks and concepts (e.g., future expectations, predictions of others' behaviors, conservation tasks) but that these difficulties are less apparent at older ages (Alvarez, Ruble, & Bolger, 2001; Case, 1991; Harter, 1996; Parsons & Ruble, 1977; Ruble, Parsons, & Ross, 1976). Piaget (1963/2001; Siegler & Alibali, 2004) attributed these changes to a shift from the preoperational stage of reasoning to a concrete operational stage, which involves more abstract thinking and use of symbolic concepts beginning at about age 7. Although previous cognitive development research focused on the idea that children develop through discrete, qualitative stages, researchers currently emphasize that children steadily become better and more efficient information processors as the brain develops a greater capacity for more complicated procedures (e.g., parallel processing; Siegler & Alibali, 2004). Evidence of mental capabilities that children did not possess at earlier ages continues well into adolescence (Keating, 2004).

This revised view does not mean, however, that development is linear. For example, some dramatic changes appear to occur between the ages of 5 and 8, making this an important focus for research (Siegler & Alibali, 2004). Indeed, 8-year-olds have become the most commonly used age group in studies of children's ability to reason about themselves and others (Alvarez et al., 2001; Harter, 1996). Researchers have referred to this change as the "5–7 year shift" (Sameroff & Haith, 1986; White, 1970). White (1996), for example, referred to the time period after the age of 7 as entering the "age of reason." Historically, ages 5–7 have been regarded as an important turning point distinguishing childhood from early adulthood because of the changes in the mental ability of the child. However, there is also research to suggest that adolescence may be a key time of change as children's cognitive development continues to mature and shifts to reasoned action and reflection (Keating, 2004). It is important when examining children's beliefs to know whether or not significant shifts occur in children's ability to understand and then report on their beliefs across time in order to understand when these beliefs might influence behavior.

Development of Belief–Behavior Relations

Though few direct tests exist of the developmental change in belief–behavior relations, differences in belief–behavior connections before and after 8 years of age have been reported frequently. Findings from developmental research suggest that younger children's beliefs and behaviors may be only negligibly related before the age of 7 (Parsons & Ruble, 1977; Spencer & Bornholt, 2003) and that beliefs are unreliable predictors of future behaviors until after the age of 8 (Huesmann & Guerra, 1997). This phenomenon has been documented in research on such diverse domains as self-esteem (Davis-Kean & Sandler, 2001), expectancies regarding success and failure (Parsons & Ruble, 1977), beliefs about the acceptability of aggression (Huesmann & Guerra, 1997), and social information processing in relation to externalizing behavior (Lansford et al., 2006). These arrays of findings give some indication that the relations between self-efficacy beliefs and behaviors may vary across development.

Further support comes from research on expectancies for success and failure. Parsons and Ruble (1977), for example, showed that older children incorporated information regarding their outcomes quickly and changed their predictions about future successes or failures accordingly, whereas children younger than age 8 typically did not. This is consistent with developmental work by Harter (1999) suggesting that possible cognitive limitations to young children's ability to answer these types of questions (self-reflective) at earlier ages.

These findings, though suggestive, do not constitute direct evidence on the question of whether stability or change occurs in the relation between self-efficacy beliefs and behaviors across development. In order to test for stability, one would need to examine the synchronous correlations between self-efficacy behavioral beliefs and their associated behaviors and see if they differ across time. If they do not significantly differ across time, then these relations are stable. Conversely, if the synchronous correlations do significantly differ across time, then these relations are changing and it will be important to specify at what age these relations may be changing.

The current study is intended to describe and test whether or not the relations between self-efficacy beliefs and behaviors stay stable or change across time. We examine these relations across time by using information from multiple data sets and multiple belief domains. If the relations change, are the relations weaker in childhood than in adolescence, as previous research appears to suggest or do the associations differ from one age period to another across early childhood, middle childhood, and adolescence? An important consideration in examining these changes is whether reliability of the measures is a factor in the change, such that younger children are less reliable in their answers, thus attenuating the correlations between beliefs and behaviors (Davis-Kean & Sandler, 2001; Trzesniewski, Donnellan, & Robins, 2003).

We use two different longitudinal data sets with observations collected both in childhood and in adolescence. In these data sets, we have information on two different behaviors (i.e., academic achievement and aggressiveness) and self-efficacy beliefs regarding these behaviors (e.g., self-concept of ability and self-efficacy of aggression). Thus, a unique feature of this study is that we will test the generalizability of change in associations between self-efficacy beliefs and behaviors both through analyzing two independent data sets and by using two different important childhood outcomes.

Method

The data sets for the study come from a collaboration of longitudinal researchers who have made their data sets available to answer and replicate developmental questions. The data sets selected for the analyses met two criteria. First, both had been guided by theories (e.g., information processing theories, expectancy-value theory) positing similar self-efficacy belief–behavior relations across development. Thus, the researchers had collected data that measured beliefs and behaviors on multiple occasions across childhood and adolescence. Second, the self-efficacy beliefs and behaviors were assessed in a similar manner across time. The two data sets that met these criteria and their relevant methodology are summarized below.

Data Sets and Measures

Childhood and Beyond (CAB). Three cohorts of children from 28 schools located in four southeastern Michigan school districts provided data for the current analysis (Eccles, Wigfield, Harold, & Blumenfeld, 1993). Academic belief (math self-concept of ability) and behavior (math grades) data were collected starting in the fall and spring of the 1988–1989 school year, respectively, from children in Grade 1 ($n = 317$), Grade 2 ($n = 330$), and Grade 4 ($n = 423$) each year for 3 years. In a follow-up study starting in 1994, data were collected from these cohorts each year for 3 years. Thus, the Grade 1 cohort has data from six periods (Grades 1, 2, 3, 7, 8, and 9), the Grade 2 cohort has data from six periods (Grades 2, 3, 4, 8, 9, and 10), and the Grade 4 cohort has data from six periods (Grades 4, 5, 6, 10, 11, and 12). Ninety-three percent of participants in the sample are Caucasian, 50% are female, and all generally were of relatively high socioeconomic status (SES).

Self-concept of math ability (SCMA) and math grades served as the primary belief and behavior variables of interest, respectively. SCMA is a composite variable that includes five items: "How good at math are you?" "If you had to list all the students from best to worst in math where are you?" "Compared to other subjects how good are you at math?" "How well do you expect to do in math this year?" and "How good would you be at learning something new in math?" Responses were measured on a Likert-type scale ranging from 1 to 7 (e.g., 1 = *one of the worst*, 7 = *one of the best*) and collected in the spring of the child's academic year. SCMA Cronbach's alphas were .76, .79, .85, .90, .92, and .93 for Waves 1 through 6, respectively.

Math grades were obtained from school records. In the first three waves, math grades correspond to the child's math performance during the spring only; in the latter three time periods, the child's final math grade for the academic year was used. Grades were coded on a scale of 1–16 where 1 represented an F− and 16 an A+. The grades ranged between 1 and 16 for the Grade 1 cohort, between 3 and 16 for the Grade 2 cohort, and between 1 and 16 for the Grade 4 cohort.

Child Development Project (CDP). The families in the CDP (Dodge, Bates, & Pettit, 1990) were recruited when the children entered kindergarten in 1987 or 1988 at three sites: Knoxville and Nashville, TN, and Bloomington, IN. The combined sample consisted of 585 families at the first assessment. Males comprised 52% of the sample. Eighty-one percent of the sample were Caucasian, 17% were African American, and 2% were from other ethnic groups. Follow-up assessments used in the present study were conducted in Grades 1–3, 8, and 11, giving a total of six waves of data. Compared to the original sample, the families who provided data in Grade 11 (78% of the original sample) were of slightly higher SES, but participants and nonparticipants did not differ by race, single-parent status, or mothers' reports of children's externalizing behaviors in kindergarten.

In Grades kindergarten through 3, children were presented with a series of four cartoon pictures and brief verbal descriptions of the cartoon events. In each cartoon, children were told to imagine being the protagonist. After hearing the description of each event, children were presented with alternative strategies (competent, aggressive, and inept) for dealing with the situation. Efficacy for aggression was assessed by asking children to rate how easy it would be for them to act aggressively in each situation (1 = *HARD*, 2 = *hard*, 3 = *easy*, 4 = *EASY*). Efficacy for aggression was scored as the average of this item following the aggressive response across the four vignettes. Cronbach's alphas for this measure in Grades 1–3 were .64, .59, and .55, respectively. In Grades 8 and 11, participants were shown six video vignettes that started with a social interaction and culminated in an ambiguous provocation by peers or adults directed toward a protagonist adolescent. Participants were asked to imagine being the protagonist. Three vignettes depicted provocations that were relevant to both boys and girls and were presented to all participants; the remaining three vignettes were sex specific. Each provocation segment was followed by two segments that presented an aggressive and a nonaggressive response to the provocation, respectively. After each of the responses presented on the video, efficacy for aggression was assessed by asking adolescents how easy it would be for them to act aggressively in each situation (1 = *very hard*, 5 = *very easy*). A composite variable was created in Grade 8 and Grade 11 by averaging this item from the aggressive responses across the six vignettes. Cronbach's alphas for these measures were .82 and .86, respectively.

Mothers completed the Child Behavior Checklist (CBCL; Achenbach, 1991) annually when their children were in kindergarten through grade 11. Mothers reported whether each item was 0 = *not true*, 1 = *somewhat or sometimes true*, or 2 = *very or often true* of the child. The 20 items in the aggression subscale were summed to create a separate scale for each year. Cronbach's alphas were high and stable (.87, .87, .87, .89, .89, .90 for Waves 1 through 6, respectively).

Attrition and Missing Data Plan

The problem of missing data is inherent in the use of longitudinal data sets. Each of the data sets used in this study had various amounts of missing data—ranging from a low amount of missing (CDP ~ 5%) to a rather high amount of missing (CAB ~ 40%). In order to minimize bias due to attrition, the CAB and CDP missing data were multiply imputed using the NORM program (Schafer, 1999). Compared to other missing data procedures, multiple imputation (MI) is superior when it comes to minimizing bias due to attrition (Graham, Hofer, & Piccinin, 1994; Little & Rubin, 1987; Schafer & Olsen, 1998). In the same regard, MI is also far superior to simple casewise deletion (Little & Rubin, 1987; Schafer & Olsen, 1998). Moreover, not only are the parameter estimates more trustworthy when using MI (due to its accounting for attrition more effectively) but also standard errors associated with the parameter estimates are not artificially decreased, and as such inferences are trustworthy as well (Graham et al., 1994; Schafer & Olsen, 1998).

One assumption of the MI procedure is that all variables included in the procedure are approximately normally distributed (Schafer & Olsen, 1998). Any data with violations of normality (e.g., aggressive behavior variables) were transformed prior to imputation. A second assumption of the MI procedure is that the data imputed are missing at random. When utilizing MI, the first step is to empirically identify as many variables as possible that are related to the missingness of the variables to be imputed. Once identified, these variables are included in the imputation process as "auxiliary variables," and their inclusion helps to ensure that the imputed data resulting from the MI procedure are unbiased. However, once the data are imputed, the auxiliary variables are dropped, and the imputed data are then analyzed separately from the auxiliary variables. Because the auxiliary variables are not included in the actual analyses, they are not equivalent to control variables.

Separately for CAB and CDP, the number of missing time points for each variable was used as a grouping variable, and a series of one-way analyses of variance were conducted to determine what auxiliary variables were significantly related to missingness. Several auxiliary variables were identified and incorporated into the MI model for both data sets, including SES indicators (i.e., income, education, and occupation), IQ measures (e.g., Slossan, Wechsler Intelligence Scale for Children–Revised), sex, race/ethnicity, and demographic location variables such as neighborhoods or school districts.

Due to the cohort-sequential design of CAB, there are many instances of planned missingness (e.g., a respondent is missing data due to the design of the study as opposed to nonresponse). In instances of planned missingness, data were not imputed. For example, due to the design of the study, no respondent in the first cohort of CAB provided data at Grades 4, 5, 6, 10, 11, and 12. Thus, individuals in the first cohort of CAB did not have data imputed at these grades, and instead only had data imputed for the grades where data were actually collected (Grades 1, 2, 3, 7, 8, and 9). In a similar fashion, for the remaining two CAB cohorts, data were imputed only for the grades where data were actually collected. For each respondent, data were imputed at the individual item level (as opposed to the scale level). This was done for three reasons. First, when using MI and imputing scale data, it is standard practice to carry out those imputations at the item level (Schafer & Olsen, 1998). Second, when possible, we model the multiitem scales as latent constructs in our structural equation models, and therefore, our analyses demand item-level data. Finally, as is standard practice when utilizing MI (Graham et al., 1994; Schafer & Olsen, 1998), in instances where respondents had complete missing data for a given measure at a particular grade (whether based on a single-item or a multiitem scale), and that complete missingness was not due to planned missingness, data were imputed.

Among the 1,070 respondents included in the CAB analyses, the mean percentage missing across the 36 measures for which missing values were imputed (five observations for the math self-concept of ability scale at six time points and one observation of grades at six time points) was 40.1%. Based on this fraction, eight data sets were imputed to reach an efficiency level above .95 (Rubin, 1987). Among the 585 respondents included in the CDP analyses, the mean percentage missing across the 148 measures for which missing values were imputed (20 observations for the CBCL at six time points, 4 observations for the efficacy for aggression scale at the four initial time points, and 6 observations for the efficacy for aggression scale at the last two time points) was 5.3%. Based on this fraction, only three data sets needed to be imputed in order to reach an efficiency level above .95 (Rubin, 1987); however, because five imputed data sets is the standard minimum for number of imputed data sets (Schafer & Olsen, 1998), five data sets were imputed to reach an efficiency level well above .95.

Analysis Strategy

Imputed means and estimates of their standard errors were calculated using PROC MIANALYZE within SAS (SAS Institute, 1999), which was developed to estimate standard errors of multiply imputed data. All analyses were conducted within Mplus (Muthen & Muthen, 1998–2006), using the imputation option developed for multiply imputed data.

In order to assess if the association between SCMA and math grades changes over time, we used the quasi-simplex measurement model presented in Figure 1. In order to asses if the relation between efficacy for aggression and aggressive behavior changes over time, we used the quasi-simplex measurement model presented in Figure 2. First, the models in Figures 1 and 2 are measurement models (as opposed to causal path models) because there are no causal paths in either model and, instead, only correlations are included. The inclusion of causal paths (say, autoregressive paths) would answer a different question—namely, "how does the relationship between changes in beliefs and changes in behaviors between time *t* and time *t*−*1* itself change over time?"

Second, the models in Figures 1 and 2 are both quasi-simplex models because in both models the behavior measure (i.e., math grade for the model in Figure 1 and aggressive behavior for the model in Figure 2) is based on a single indicator. Within a quasi-simplex model, in order to adjust for the reliability of each measure at each time point, errors are fixed based on the following equation: $e = \sigma^2[1 - \alpha]$ (Joreskog, 1970). For the model in Figure 1, the measure for behavior (i.e., final math grade) is based on a single indicator; as such the interitem reliability between fall math grade and final math grade was used as a proxy measure for interitem reliability (allowing for the fact that grades generally represent a true score with some error). For each of the six points in time, a given point in time's interitem reliability between fall math grade and final math grade was applied. Across the six time periods, the alphas were .85, .85, .88, .95, .96, and .96, respectively. For the model in Figure 2, the measure for behavior (i.e., aggressive behavior) is based on the aggregate of 20 CBCL indicators for which the interitem reliability at each time point was applied. Across the six periods, the alphas were .87, .87, .87, .89, .89, and .90, respectively. For both of the latent behavior constructs (math grades and aggressive behavior), it is not possible to correlate the error variances of matching items across time because they are based on a single observed indicator (Marsh, 1993). However, for both the latent belief constructs (SCMA and efficacy for aggression), which were based on multiple observed indicators, the error variances of matching items were correlated across time.

In order to empirically assess whether or not the relation between behaviors and beliefs changes over time, we compared models where the synchronous covariances between beliefs and behaviors are constrained to be equal across time to models where the synchronous covariances are free to vary across time.

Figure 2. Estimates for quasi-simplex measurement model assessing relationship between aggression self-efficacy and aggression over time, Child Development Project.
Note. Important correlations are bolded for emphasis. Solid lines indicate significance at .05 level. EFF short for aggression self-efficacy; AGG short for aggression. For EFF, exogenous arrows represent indicators listed in Table 2. Fit indices: $\chi^2(922) = 1,682.52, p < .001$; comparative fit index = .90; root mean square error of approximation = .05.

According to convention, model comparisons were based on changes in chi-square relative to changes in degrees of freedom (Kline, 1998). The chi-square value used in the model comparisons is the chi-square value provided in the Mplus output, which is the average chi-square value (Muthen, 2005) across the *m* data sets, where m is the number of imputed data sets.

Results

Basic Descriptive Statistics

The imputed means and standard deviations for all measures for CAB and CDP are presented in Table 1. The means and standard deviations are presented separately for each cohort. The factor loadings for the latent belief constructs, math self-concept of ability (CAB), and efficacy for aggression (CDP), and the latent behavior constructs, math grades, and aggressive behavior, were computed from the measurement models in Figures 1 and 2 and are listed in Table 2. Also listed in Table 2 are the residual variances for each observed variable included in the measurement models in Figures 1 and 2. Because there are eight imputed data sets for CAB and five imputed data sets for CDP, there are 13 covariance matrices in all. As such the covariance matrices are not presented here but are available from the authors upon request.

Changes in Synchronous Correlations Between Math Self-Concept and Math Grades

Before examining whether or not the association between math self-concept and math grades shown in Figure 1 changes over time, we tested for cohort and sex differences in the relations shown in the model. First, we tested for cohort differences. Specifically, a fully unconstrained model (Model 1, Table 3) where all covariances were free to vary across the three cohorts was compared to both a model where just the synchronous covariances were constrained to be equal across the three cohorts (Model 2, Table 3) and a model where all covariances were constrained to be equal across the three cohorts (Model 3, Table 3). The χ^2_{diff} test showed that these models differed significantly from each other, and therefore, it was not tenable that these associations were same across the cohorts, Model 2, $\chi^2_{\text{diff}}(12) = 60.37, p < .001$, and Model 3, $\chi^2_{\text{diff}}(52) = 197.19, p < .001$. Next, we tested for sex differences. Again, we compared a fully unconstrained model (Model 4, Table 3) where all covariances were free to vary across sex to both a model where just the synchronous covariances were constrained to be equal across sex (Model 5, Table 3) and a model where all covariances were constrained to be equal across sex (Model 6, Table 3). The fit of Model 4 (the fully unconstrained model) did not fit the data any better than did Model 5, $\chi^2_{\text{diff}}(6) = 7.96, p = .24$, or

How easy would it be for you to act like this? (Vignette 5)					.766 (.41)	.595 (.65)
How easy would it be for you to act like this? (Vignette 6)					.674 (.54)	.747 (.44)
Child Behavior Checklist (CDP)	.933 (.13)	.933 (.13)	.932 (.13)	.944 (.11)	.945 (.11)	.946 (.11)

Note. Residual variances in parentheses. CAB = Childhood and Beyond Study; CDP = Child Development Project.

Model 6, $\chi^2_{\text{diff}}(26) = 35.18$, $p = .11$, and the χ^2_{diff} test did not significantly differ from the unconstrained model. Thus, we can conclude that the associations between math self-efficacy and math grades did not differ across sex.

Given these findings, we proceeded to estimate the simplex model of relations between math self-efficacy and math grades across grades separately for each cohort with the parameters constrained to be equal across males and females. The resulting parameter estimates are shown in Figure 1 (note that the standardized estimates or correlations are presented opposed to the unstandardized estimates or covariances). The estimates for the synchronous correlations between math self-concept and math grades are of key interest. In order to test if the synchronous correlations vary over time, we conducted a series of model comparisons. First, we compared a model where all synchronous covariances were free to vary across time (Model 7, Table 3) to a model where all synchronous covariances were constrained to be equal across time (Model 8, Table 3). Model 7 (where synchronous covariances were allowed to vary across time) fit the data better than did Model 8, $\chi^2_{\text{diff}}(15) = 272.20$, $p < .001$. Thus, the association between math self-concept and math grades does vary across time. Next, guided by our expectation that the association between beliefs and behaviors would be markedly higher during adolescence than during childhood, we compared a model where all synchronous covariances between Grade 1 and Grade 5 (i.e., childhood) were constrained to be equal and all synchronous covariances between Grades 6 and 12 (i.e., adolescence) were constrained to be equal (Model 9, Table 3) to the more parsimonious Model 8 (Table 3). Model 9 fit the data better than did Model 8, $\chi^2_{\text{diff}}(3) = 111.66$, $p < .001$. As expected, the estimate for the synchronous association during childhood (unstandardized = .51, standardized ~ .26) was lower than the estimate for the synchronous association during adolescence (unstandardized = 1.94, standardized ~ .51). Finally, guided by our expectation that the association between self-efficacy beliefs and behaviors would also be markedly higher during late childhood (Grades 3–5) than during early childhood (Grades 1–2), we compared a model where all synchronous covariances between Grade 1 and Grade 2 (i.e., early childhood) were constrained to be equal,

Table 3
Childhood and Beyond Model Comparisons

Cohort comparison								
(1) Cohort—unconstrained model	3,339.58	1425	< .001	.919	.061			
(2) Cohort—synchronous covariances constrained	3,399.95	1437	< .001	.917	.062	60.37	12	< .001
(3) Cohort—"structural" covariances constrained	3,536.77	1477	< .001	.912	.063	197.19	52	< .001
Gender comparison								
(4) Gender—unconstrained model	2,472.67	942	< .001	.932	.055			
(5) Gender—synchronous covariances constrained	2,480.63	948	< .001	.932	.055	7.96	6	.24
(6) Gender—"structural" covariances constrained	2,507.85	968	< .001	.932	.055	35.18	26	.11
Structural comparison								
(7) Unconstrained	3,339.58	1425	< .001	.919	.061			
(8) All synchronous covariances constrained	3,611.78	1440	< .001	.908	.065	272.20	15	< .001
(9) Constraining 1st–5th versus 6th–12th	3,500.13	1437	< .001	.912	.063	111.66	3	< .000[a]
(10) Constraining 1st–2nd versus 3rd–5th versus 6th–12th	3,497.86	1435	< .001	.912	.063	2.269	2	.32[b]

Note. CFI = comparative fit index; RMSEA = root mean square error of approximation.
[a] Model comparison is based on comparing Model 9–Model 8 (i.e., Model 9 fits better).
[b] Model comparison is based on comparing Model 10–Model 9 (i.e., Model 9 and 10 fit equally well).

all synchronous covariances between Grades 3 and 5 were constrained to be equal (i.e., late childhood), and all synchronous covariances between Grades 6 and 12 (i.e., adolescence) were constrained to be equal (Model 10, Table 3) to the more parsimonious Model 9 (Table 3). Model 10 did not fit the data any better than did Model 9, $\chi^2_{\text{diff}}(2) = 2.27$, $p = .32$. Thus, the synchronous correlations between math self-efficacy and math grades do not appear to differ between early childhood and late childhood.

Changes in Synchronous Correlations Between Efficacy for Aggression and Aggressive Behavior

Again, before examining whether or not the association between efficacy for aggression and aggressive behavior changed over time, we tested for cohort and sex differences in the measurement model presented in Figure 2. First, we tested for cohort differences. Specifically, a fully unconstrained model (Model 1, Table 4) where all covariances were free to vary across the two cohorts was compared to both a model where just the synchronous covariances were constrained to be equal across the two cohorts (Model 2, Table 4) and a model where all covariances were constrained to be equal across the two CDP cohorts (Model 3, Table 4). The fit of Model 1 (the fully unconstrained model) was not significantly better than either Model 2, $\chi^2_{\text{diff}}(6) = 8.53$, $p = .20$, or Model 3, $\chi^2_{\text{diff}}(26) = 35.93$, $p = .09$. Thus, we concluded that the associations between self-efficacy for aggression and aggressive behavior did not differ across the two CDP cohorts. Next, we tested for sex differences by comparing a fully unconstrained model (Model 4, Table 4) where all covariances were free to vary across sex to both a model where just the synchronous covariances were constrained to be equal across sex (Model 5, Table 4) and a model where all covariances were constrained to be equal across sex (Model 6, Table 4). The fit of Model 4 (the fully unconstrained model) did not fit the data any better than did Model 5, $\chi^2_{\text{diff}}(6) = 8.35$, $p = .21$, or Model 6, $\chi^2_{\text{diff}}(26) = 28.95$, $p = .31$. Thus, we concluded that the associations between self-efficacy of aggression and aggressive behaviors (including synchronous correlations) did not differ across sex.

Given these findings, we proceeded to estimate the simplex model of relations between self-efficacy of aggression and aggressive behaviors with the parameters constrained to be equal across sex and cohort. The resulting parameter estimates are shown in Figure 2 (note that the standardized estimates or correlations are presented opposed to the unstandardized estimates or covariances). The estimates for the synchronous correlations between self-efficacy of aggression and aggressive behaviors are of key interest. In order to test if the synchronous correlations vary over time, we conducted a series of model comparisons. First, we compared a model where all synchronous covariances were free to vary across time (Model 7, Table 4) to a model where all synchronous covariances were constrained to be equal across time (Model 8, Table 4). Model 7 (where synchronous covariances were allowed to vary across time) fit the data better than did Model 8, $\chi^2_{\text{diff}}(5) = 49.65$, $p < .001$. Thus, the association between self-efficacy of

[b] Model comparison is based on comparing Model 10–Model 9 (i.e., Model 10 fits better).

aggression and aggressive behaviors does vary across time. Next, guided by our expectation that the association between beliefs and behaviors would be markedly higher during adolescence than during childhood, we compared a model where all synchronous covariances between kindergarten and Grade 3 (e.g., childhood) were constrained to be equal and all synchronous covariances between Grades 8 and 11 (i.e., adolescence) were constrained to be equal (Model 9, Table 4) to the more parsimonious Model 7 (Table 4). Model 9 fit the data better than did Model 7, $\chi^2_{\text{diff}}(1) = 34.99$, $p < .001$, demonstrating that the relations between self-efficacy of aggression and aggressive behavior were similar within childhood and within adolescence but differed between childhood and adolescence. As expected, the estimate for the synchronous association during childhood (unstandardized = .00, standardized $\sim$ .01) was lower than the estimate for the synchronous association during adolescence (unstandardized = .06, standardized $\sim$ .30). Finally, guided by our expectation that the association between beliefs and behaviors would be markedly higher during late childhood (Grades 3) than during early childhood (kindergarten—Grade2), we compared a model where all synchronous covariances during early childhood were constrained to be equal, all synchronous covariances during late childhood were constrained to be equal, and all synchronous covariances during adolescence where constrained to be equal (Model 10, Table 4) to the more parsimonious model 9 (Table 4). Model 10 fit the data better than did Model 9, $\chi^2_{\text{diff}}(1) = 11.17$, $p < .001$. As expected, the synchronous association during late childhood (unstandardized = .04, standardized $\sim$ .15) was higher than the synchronous association during early childhood (unstandardized = .00, standardized = −.02) but lower than the synchronous association during adolescence (standardized = .06, unstandardized $\sim$ .30).

Discussion

Decades of theoretical and empirical developmental research have suggested that a cognitive-developmental shift in middle childhood may account for well-documented differences between cognitive functioning in early and later childhood (Case, 1991; Harter, 1996; Sameroff & Haith, 1986). Among these developmental progressions are several that involve how children think about and judge the behaviors of self and others (Flavell & Miller, 1998; Wellman, Cross, & Watson, 2001). This article presents evidence of a similar developmental progression in links between children's self-efficacy beliefs and their own behaviors. Although many theoretical models in the social sciences imply that this link should be stable across development (Crick & Dodge, 1994; Fazio, 1995), our results suggest that, at least in the case of some self-efficacy beliefs, this assumption is not tenable.

Underlying this conclusion are our findings that the relation between beliefs in two different psychological domains (self-concept of ability for math, self-efficacy for aggression) and behaviors (grades, mother reports of child aggression) increases with development independently of the ability to measure the constructs. It is notable that these relations do not differ by sex for either math achievement or aggression where we might have expected differences to exist.

Another strong finding is that these changes replicate in four independent samples. In the case of math achievement, three independent cohorts assessed with the same self-efficacy and behavior measures across time showed the same shift in relations between childhood and adolescence and also displayed very similar relations at the same point in development (grade). The same findings replicated for self-efficacy of aggression and aggressive behaviors with two independent cohorts. Interestingly, when examining aggression beliefs and behaviors, there appears to be an additional significant shift in the relations between early childhood and middle childhood. Thus, there does appear to be an important adolescent change in the relation between self-efficacy beliefs and behaviors for both achievement and aggression beliefs but an additional shift for aggression beliefs in middle childhood. Examining whether this shift is consistent with cognitive-developmental changes that are being seen in early adolescence (Keating, 2004) will be an important avenue of research to pursue in the future.

One of the many challenges in explaining this change is accounting for the possibility that the reliability of the relevant measures may increase across time, thus producing the more stable age-related relations. Previous research has indicated that reliabilities and stability in measurement do increase by age (Davis-Kean & Sandler, 2001; Guay, Marsh, & Boivin, 2003; Trzesniewski et al., 2003), though even young children appear to respond reliably in these domains and can even make complicated differentiations across multiple aspects of the self (Marsh, Debus, & Bornholt, 2005). To rule out measurement unreliability as an alternative explanation for the present findings, our analyses corrected for attenuation by using latent variables with multiple indicators in structural equation models. Furthermore, as can be seen in the Method section, the internal reliability coefficients at both the earliest and the later ages showed adequate to good internal reliability. Similarly, the within-construct correlations across time (i.e., the extent to which beliefs and behaviors correlated with themselves across time) were both sizable and stable, revealing that belief and behavior structures remain relatively stable across time. Thus, the measures across the studies appear to be generally good indicators of the constructs measured, and the observed changes in the concurrent relations across time are unlikely to be due to changes in the reliability of the measures.

Developmental psychologists have demonstrated that children are capable of certain thoughts and actions well before the classic Piagetian stages would have predicted them (Gelman & Baillargeon, 1983). However, isolating a reliable developmental progression in belief – behavior relations implies both groups have been correct in concluding that the early development of beliefs is a precursor to later knowledge about the self. This knowledge, however, may only become accessible and predictive at a certain point in development (Harter, 1999).

The present findings thus underscore the importance of several methodological issues for future studies of belief – behavior relations. Our data rely on self-report methods of self-efficacy beliefs, and the observed changes in synchronous relations can only be generalized to other self-report findings. Similarly, beliefs other than self-efficacy beliefs should be examined to determine whether belief – behavior relations vary across types of self-beliefs. As Wellman et al. (2001) have found, false beliefs are well established by the age of 5, and thus we would not necessarily expect to see these types of changes in relations across time in tasks related to false beliefs.

Even with these limitations, the findings underscore the importance of several methodological issues for future studies of belief – behavior relations. Questions of how and when in development these phenomena should be measured also remain important for future research endeavors. Should researchers collect self-report data on self-conceptions of beliefs if the purpose is to predict behavior, especially in cross-sectional data collection? The fact that the beliefs data in the present study are self-reports from children, whereas the behavior indicators are school records and reports from parents constitutes both a strength and weakness for interpreting the analyses. Using reports from others or school records avoids the method variance problems that occur when measures of both the independent and the dependent variables come from self-reports of study participants. Experimental studies would potentially permit testing these hypotheses directly and give us additional information on the potential mechanisms underlying the change in the relations between beliefs and behaviors across time.

Despite these remaining challenges, the present evidence of changes across time in the connection between self-efficacy beliefs and behaviors is a potentially significant advance in understanding the nature of belief – behavior relations. That the finding is robust across multiple belief–behavior domains (achievement and aggression) and using different measures of behavior (grades, parent reports of aggression) strengthens the contribution of the work as a useful beginning point for understanding this phenomenon and its implications for future research on theory and methods. Finally, confirming relatively late increases in stability implies the possibility of intervening with young children at risk for potentially dysfunctional behavior-relevant beliefs. If children's beliefs regarding their academic performance or the appropriateness and effectiveness of certain behavioral strategies are in formation well into the school years, clinicians have a window of opportunity during which interventions directed toward these beliefs might lead to more positive and successful behaviors in the future.

Categories Influence Predictions About Individual Consistency

Marjorie Rhodes and Susan A. Gelman
University of Michigan

Predicting how people will behave in the future is a critical social-cognitive task. In four studies ($N = 150$, ages preschool to adult), young children (ages 4–5) used category information to guide their expectations about individual consistency. They predicted that psychological properties (preferences and fears) would remain consistent over time after hearing one example in which properties followed a category-linked distribution (e.g., children of different genders had different properties) but not when properties varied within a category (e.g., children of the same gender had different properties). The developmental course of these findings is examined. Results suggest the importance of considering how children's emerging theories of behavior and of social groups operate together to inform their expectations about the social world.

To an adult, hearing a child say that she "likes Winnie the Pooh" provides valuable information. For example, the adult may use this information to select birthday presents for this child or to choose books to offer to read to her. These inferences are possible because adults interpret the child's statement as stemming from a stable disposition toward Winnie the Pooh and expect this disposition to cause similar behaviors across time and situations (e.g., Yuill, 1993).

The example above demonstrates a tendency to explain human behavior by appealing to internal stable causal mechanisms, a lay theory termed *dispositionism* (Choi, Nisbett, & Norenzayan, 1999; Ross & Nisbett, 1991). Adults apply a disposition-based theory to explain and predict human behavior across a wide range of tasks, including when they have very limited information about the relevant behavior or characters (Gilbert & Malone, 1995; Uleman, 1987). A number of studies indicate, however, that preschoolers are less likely than adults to appeal to dispositions to explain behavior (Miller, 1984) or to expect individual behavior to remain stable across time and situations, especially when limited information is available (e.g., Kalish, 2002).

The goal of the present article was to examine how preschoolers approach the task of explaining and predicting behavior when they have little evidence to draw on. If young children viewed most brief observations of behavior in their everyday lives as uninformative about the future, they would have some difficulty establishing a general sense of people and their roles, which would be a considerable impediment to learning from their environment. In the present work, we examined the possibility that preschoolers rely on category knowledge to make predictions about individual future behavior. In doing so, we aimed to enrich our understanding of young children's social inferences, by examining the circumstances in which they do and do not expect people to be consistent over time, as well as to examine a previously unexplored way that categories may guide induction in early childhood.

Dispositional Thinking in Early Childhood

Previous research from the related area of trait concepts suggests that dispositional thinking is accessible to preschool children under certain circumstances (e.g., Cain, Heyman, & Walker, 1997; Heyman & Gelman, 2000) but also that young children require more (or different kinds of) evidence than adults do to engage in such reasoning (Aloise, 1993; Boseovski & Lee, 2006; Miller & Aloise, 1989). Much of the research examining dispositional thinking has tested whether children and adults use information about past experiences to guide predictions about the future. For

example, researchers have examined whether learning that a girl liked chocolate cookies in the past leads participants to predict that she will like chocolate cookies again in the future (Kalish, 2002) or whether learning that a boy acted generously in one situation will lead participants to predict that he will act generously again in a different situation (Rholes & Ruble, 1984). On such questions, participants are often provided with relatively limited information about an actor's behavior (e.g., one example). Under these conditions, adults readily expect preferences and traits to be consistent over time, whereas children younger than age 7 demonstrate chance-level responding (Kalish, 2002; Kalish & Shiverick, 2004; Lawson & Kalish, 2006).

Using other methods, however, such as providing young children with many detailed examples of distinctive past behavior (Boseovski & Lee, 2006; Cain et al., 1997; Ferguson, van Roozendaal, & Rule, 1986; Gnepp & Chilamkurti, 1988), more sensitive response measures (Dozier, 1991), or linguistic cues (Gelman & Heyman, 1999), researchers have found that even 4-year-olds will predict behaviors and traits to be consistent over time. Also, a number of studies indicate that preschoolers can use trait terms to make predictions about behavior (Heyman & Gelman, 1999, 2000; Liu, Gelman, & Wellman, 2007) and that 3- and 4-year-olds can label examples of behavior with appropriate trait terms (Boseovski & Lee, 2006; Liu et al., 2007), indicating some facility with dispositional thinking when experimental tasks are simplified (but see Alvarez, Ruble, & Bolger, 2001; Yuill & Pearson, 1998, for alternate interpretations of preschoolers' success on tasks measuring dispositional thinking).

Kalish (2002) addressed preschoolers' hesitancy to predict consistency based on limited evidence, in spite of their knowledge of dispositions revealed on some tasks, with two proposals: (a) individuals predict consistency only when they view the event in question as resulting from a stable causal mechanism that is likely to cause the event again, and (b) preschoolers are less likely than adults to view behaviors as resulting from stable dispositions. That is, dispositions are not salient causal mechanisms within young children's theories of social behavior. Instead, Kalish suggests that young children are more likely to appeal to temporary factors to explain human behavior, such as passing desires and individual volition, and may not understand the role of stable dispositions in constraining those factors (see also Wellman, 1990). Thus, in the example given at the beginning of this article, preschoolers may conclude that the character said she liked Winnie the Pooh because she wanted to (e.g., felt like saying it), wanted Winnie the Pooh at that moment, or liked Winnie the Pooh for an external reason, such as a rule or adult request (Kalish & Shiverick, 2004; Karniol & Ross, 1976). In other words, they may not take this statement as evidence of a stable disposition toward Winnie the Pooh (see also Yuill, 1997). Because the character's preference is not viewed as resulting from a stable mechanism, preschoolers are unlikely to predict that the preference will be stable over time.

Within the framework described by Kalish (2002), it is not necessary to view dispositionism as entirely absent from young children's thinking; rather, it may be that young children require more clues before inferring the presence and importance of dispositions. For example, preschoolers may not view dispositions as relevant to as many behaviors as adults do or they may not view dispositions as common within human psychology. Thus, they would be less likely to appeal to dispositions to explain behavior if presented with little information. From this perspective, adults are more ready to predict consistency in social behavior because of the increased salience of dispositions within their naïve theories (e.g., Miller, 1984).

Category-Based Social Reasoning

We propose that when young children do not appeal to dispositions to predict behavior, they may incorporate their knowledge of other causal mechanisms into their social reasoning to make inferences. Preschoolers perceive membership in social categories, in gender categories in particular, as salient and powerful predictors of behavior. For example, Gelman, Collman, and Maccoby (1986) found that 4-year-olds expected two individuals of the same gender to share novel physical and behavioral properties, even when they were perceptually dissimilar. Similarly, Berndt and Heller (1986) found that 5-year-olds relied on gender categories to predict what sorts of activities characters would engage in (expecting them to engage in gender-typical more than gender-atypical behavior), even when they were told that characters had previously made gender-atypical behavioral choices (see also Biernat, 1991). In this case, kindergarteners relied more heavily on gender categories than adults did; adults attributed greater predictive power to characters' previous behaviors than to gender. Preschoolers also predict that children will display stereotypical gender behavior even if they are raised entirely by members of the other gender, whereas adults account for environmental influence in the development of gender-typical behavior (Taylor, 1996; Taylor, Rhodes, & Gelman, in press).

As discussed in detail by Lawson and Kalish (2006), preschoolers' willingness to base inferences on single pieces of evidence on category-based induction tasks, such as those involving gender, is in stark contrast to their hesitancy to use a single piece of evidence to make an inference about an individual over time. Preschoolers appear to consider membership in certain categories as predictive of a wide range of properties, such that they expect members of the same category to share many nonobvious properties, even if they differ from each other in other ways, such as physical appearance (for a review, see Gelman, 2003). Further, preschoolers expect membership in these informative categories to remain stable over time, regardless of environment (Gelman & Wellman, 1991; Hirschfeld, 1996; Taylor, 1996). Thus, whereas preschoolers may appeal to temporary factors to explain instances of individual behavior, they appeal to a stable factor (category membership) to make predictions about properties across category members.

We propose that in addition to appealing to category-based mechanisms to predict consistency across category members, preschoolers attend to social cues that guide them to appeal to categories to understand and predict instances of individual behavior as well. In situations where preschoolers do not perceive dispositions as causing behavior, they may attend to evidence indicating that the behavior is caused by membership in an important social category (e.g., gender). If such evidence is found, we expect preschoolers to infer that the behavior is caused by membership in a gender category, and therefore, to predict that the behavior will be consistent over time. Because gender categories are salient to young children, we expect that they will conclude that gender is causally relevant to behavior based on very limited information, as well as when the relation between gender and behavior is only implicitly communicated to them. Specifically, we hypothesize that preschoolers will predict consistency in individual behavior when they learn that individuals of one gender category, and not the other, display the properties of interest.

The Present Studies

In these studies, we first developed questions about characters' preferences and choices, in which participants received limited information about characters' previous experience. All questions involved characters engaging in novel activities, such that children's prior beliefs about the particular activities would not influence their pattern of responses. These questions did not elicit disposition-based reasoning among preschoolers, consistent with prior research. Next, we presented children with questions about pairs of characters who each experienced two things and had unique reactions to them. For example, a pair of children played two games; one child liked one game, whereas the other child liked the other. In some questions, the pairs involved two children of different genders, such that a boy liked one game and a girl liked the other. In this case, we expected children to perceive the pattern as indicating that liking a particular game is causally related to gender and, therefore, to expect preferences to be stable over time. The options were never labeled as "for boys" or "for girls"; rather, children were given information about the preferences of individual male and female characters and were left to draw their own conclusions about the relation between gender and behavior. In other questions, participants were told about pairs of children of the same gender who each liked different activities. In this case, because the pattern does not imply that liking a particular activity is causally related to gender, we did not expect preschoolers to predict consistency over time.

Developmental Changes in the Use of a Category-Based Strategy

We also included older comparison groups in these experiments, in order to examine how the use of a category-based strategy to predict individual consistency changes over time. Because adults require less information than preschool children do to make dispositional inferences (Aloise, 1993), rely on a category-based strategy as often. On questions in which adults view characters' behaviors as relevant to dispositions, they should predict consistency regardless of category information.

Adults do not engage in dispositional thinking on all questions about individual behavior, however. For example, Kalish (2002) found that on questions asking whether characters would make consistent *choices* between two options that differed rather trivially (e.g., a boy who chose a blue flower over a yellow flower), adults responded randomly. This is likely because multiple strategies seem appropriate for answering this question; the boy might choose blue because of a stable disposition toward blue or he might choose yellow because he already has a blue flower (Kalish, 2002). Because no information about preferences is provided in these questions, both responses seem plausible.

We hypothesized that when adults perceive some ambiguity as to whether an actor's behavior should be considered as caused by a disposition, they too will turn to information about category membership to guide their predictions about consistency. We also hypothesized, however, that adults will appeal to category memberships only when they view the relevant categories as likely to have caused the property of interest. As reviewed above, adults view the influence of gender as less global and less deterministic than do younger children. Although adults often hold some strong gender stereotypes, in general they view gender as influencing a relatively narrower range of behaviors and view causal forces aside from gender (e.g., the environment, personality) as important predictors of behavior (Taylor, 1996). Therefore, given the paucity of information about the relation between gender and behavior presented in these questions, as well as that questions involve *novel* (i.e., nonstereotyped) behaviors, we expected that adults would be less likely than preschoolers to assume that characters' choices in these stories were caused by gender.

We included comparison questions about nonhuman animal species in order to determine whether any age-related changes in the use of a category-based strategy related to a complete shift away from viewing category-based mechanisms as relevant to individual behaviors or to developmental changes in the meaning of gender per se. These questions followed a parallel structure to all our questions about humans and gender, including questions about individual animals (e.g., one dog), pairs of same-species animals (e.g., two dogs), and pairs of different-species animals (e.g., a dog and a cat). We selected nonhuman animals because there is evidence that both young children and adults view animal species as indicating deep and fundamental differences between individuals and view many properties as causally related to membership in an animal kind (Gelman, 2003; Medin & Ortony, 1989). Therefore, we expected both preschoolers and adults to rely on species information to predict consistency (on questions in which they do not rely on dispositions).

Thus, young children were expected to reason similarly about gender categories and animal species, treating both kinds of categories as strongly influencing behavior, whereas adults were expected to show more differentiated reasoning about gender and animal species (Taylor, 1996; Taylor et al., in press). In later experiments, we also included a comparison sample of 10-year-olds to examine more precisely the development of differentiated reasoning about gender and species categories on these questions. Because we used novel properties in all questions, we were able to compare reasoning about humans and nonhuman animals directly. This research will therefore contribute to our understanding of how young children use category information to make predictions about individual consistency as well as of the influence of different kinds of categories on reasoning across development.

Overview

The aim of Study 1 was to develop a series of questions about single individuals and their psychological properties to be used in our subsequent experiments. In Study 2, we added information about category membership (of gender and animal categories) to the questions, such that preference for a particular activity either did or did not vary according to category membership. In Study 3, we expanded the type of properties and age ranges included. Finally, in Study 4, we demonstrated that preschoolers' predictions are influenced by gender categories but not by more superficial differences (i.e., shirt color).

Study 1

The goal of Study 1 was to develop questions to be used in our subsequent experiments. Participants were told about single individuals (animals or humans) who experienced two activities, had a particular response to them, and then a few days later were presented with the same two options again. We purposefully provided participants with limited information about prior behavior so that in subsequent experiments we could assess whether preschoolers engage in category-based reasoning to approach these questions. We included two types of psychological properties, preferences and choices, which we expected to differ in the extent to which they cued adults to appeal to dispositions. Thus, we hypothesized that preschoolers would demonstrate chance-level responding on all questions, whereas adults would predict consistency on questions about preferences but not on questions about choices.

Method

Participants. Participants (n = 30; 13 male and 17 female) included 14 preschoolers (M age = 4 years 8 months, range = 4 years 0 months – 5 years 7 months) recruited from private preschools and 16 adults (M age = 19 years 2 months, range = 17 years 8 months – 22 years 1 month) recruited from introductory psychology classes at a large Midwestern public university. In all studies, the samples were approximately 80% White, 15% Asian American, and 5% from other racial/ethnic backgrounds. All participants were tested individually in a quiet office (located either at the children's schools or an on-campus laboratory) by the first author or by trained female undergraduate research assistants who were blind to study hypotheses. College students received course credit for their participation.

Procedure. Participants were presented with 16 questions, including 8 questions about children (4 about boys and 4 about girls) and 8 questions about animals of various species. Half of the questions asked about characters' preferences and half asked about their choices. Thus, there were 4 questions of each of four types (e.g., human preferences, human choices, animal preferences, and animal choices). All questions followed an identical format (see Appendix A).

For example, on a question about preferences, participants were told, "Here is Tom. A few days ago, Tom did two things: Tom went flecking and Tom went tooping. Tom liked flecking. Today, Tom is doing two things again. Again, Tom is going flecking and tooping. What will Tom like today? Will Tom like flecking, like last time, or will Tom like tooping?" After one question of each type, randomly selected in advance, participants were asked, "Remind me, which did [Tom] like the first time?" This allowed us to assess whether participants were following the scenarios; no adult and only 1 child had difficulty answering any of these questions. This child missed only one control question (of four total asked) and so was retained for analyses. All questions were accompanied by simple pictures of the story character as well as by small cards with the names of the activities printed on them. Pointing was used to aid comprehension. For all questions, responses in which participants predicted that the character would act in a consistent manner were scored as 1 (the alternate response was scored as 0).

Questions were blocked by character type (animal or human child), and order of presentation of the two blocks was counterbalanced across participants. Within each block, questions were presented in a separate random order for each participant. Several precautions were taken to prevent the results from being biased by any unforeseen preferences that the participants might have had for particular nonsense words. Specifically, the order of presentation of the two activities and the selection of particular novel activities by the story character were counterbalanced for each question across participants (e.g., in the example question above, half of the participants were told that Tom liked "flecking," whereas the other half were told that he liked "tooping"). Also, pairs of nonsense words circulated throughout the question types across participants, such that each pair of words was used equally in each of the four types of questions.

Results

We first compared the proportion of questions on which participants predicted that characters would behave consistently to the proportion expected by chance (chance = .5) for each type of question, using a series of sign tests. As shown in Figure 1, on questions about preferences, preschoolers demonstrated chance-level responding (human children: *M* = 0.48, *SD* = 0.37; animals: *M* = 0.44, *SD* = 0.65), whereas adults predicted consistency more often than expected by chance (human children: *M* = 0.78, *SD* = 0.22; animals: *M* = 0.83, *SD* = 0.22). On questions about choices, preschoolers again did not predict consistency; they demonstrated chance-level responding on questions about animals (*M* = 0.37, *SD* = 0.42) and predicted consistency *less* often than expected by chance on questions about human children (*M* = 0.25, *SD* = 0.35). As hypothesized, adults also did not reliably predict consistency on questions about choices (human children: *M* = 0.41, *SD* = 0.31; animals:

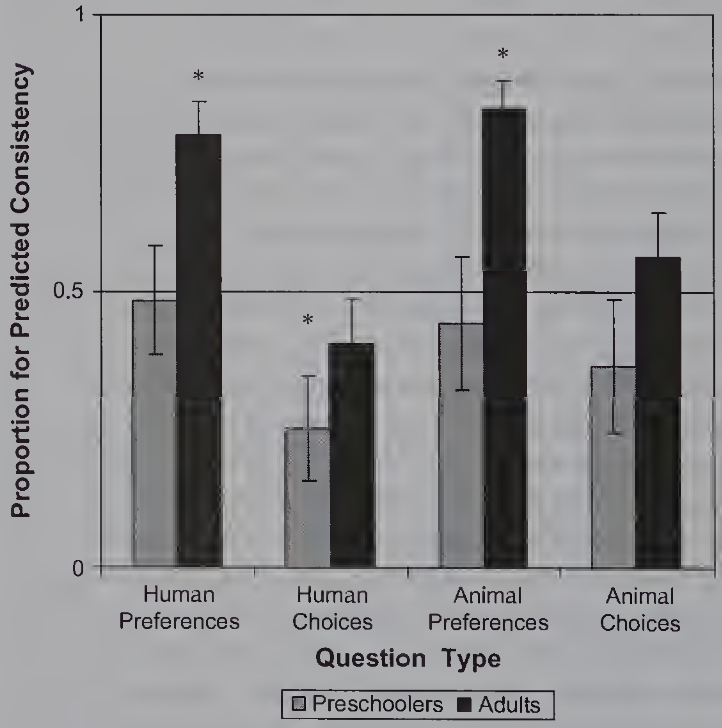

Figure 1. Proportion for predicted consistency by age and question type, Study 1.
Note. Error bars represent standard errors of the mean. Sign tests comparing the obtained proportions of predicted consistency to the proportion expected by chance.
$^{*}p < .05$.

$M = 0.56$, $SD = 0.34$). There were no main or interactive effects of participant gender or character gender, so these variables were excluded from analyses.

We next examined the data through a 2 (age: preschooler, adult) × 2 (character: human, animal) × 2 (question type: preference, choice) repeated measures analysis of variance, (ANOVA), with character and question type as within-subjects variables and age as a between-subjects variable. This analysis yielded main effects for age, $F(1, 27) = 6.12$, $p < .05$, such that adults predicted consistency more often than did preschoolers, and for question type, $F(1, 27) = 24.83$, $p < .001$, such that consistency was predicted more often for preferences than for choices. There were no other significant main or interactive effects. The interaction between question type and age was marginal, $F(1, 27) = 3.06$, $p = .09$; however, follow-up analyses indicated that the effect of age was specific to questions about preferences. As demonstrated in Figure 1, adults predicted consistency more often than preschoolers on questions about preferences, for humans, $t(28) = 2.71$, $p < .05$, $d = .99$; for animals, $t(28) = 3.0$, $p < .01$, $d = 1.10$, but not on questions about choices, for humans, $t(28) = 1.28$, *ns*; for animals, $t(28) = 1.41$, *ns*.

Discussion

The results from Study 1 support the hypothesis that preschoolers are less likely than adults to predict that preferences are consistent over time; adults strongly expected preferences to be consistent over time, whereas children responded at chance. Also, as predicted, adults did not reliably predict consistency on questions about choices. Interestingly, on the questions about human choices presented in this study as well as on some similar questions about choices asked by Kalish (2002), young children actually chose the alternate (inconsistent) response more often than expected by chance. This suggests that children may expect others to favor variety *over* consistency, especially when no preference information is provided.

Although these findings regarding children's beliefs about choices are interesting, in Study 2, we decided to ask children questions about preferences only, for two reasons. First, the aim of this series of studies was to examine whether children would use category information to guide their predictions about consistency on questions on which they otherwise would not respond in an adult-like manner, and adults reliably expected consistency only on questions about preferences. Second, pilot testing demonstrated that because the questions asked in Study 2 contained more information than those from Study 1 (see below), the task was too long for young children when questions about both preferences and choices were asked.

Based on these considerations, both preschoolers and adults in Study 2 were asked questions about preferences. For adults only, we also included supplemental questions about choices. These were included because adults' predictions of consistency on questions about preferences were relatively high, indicating that they were engaging in dispositional thinking on these questions. Therefore, we did not expect information about category memberships to influence their predictions. Results from Study 1 indicated, however, that they did not engage in dispositional thinking on questions about choices; therefore, adding category information to these questions allowed us to test the hypothesis that adults are influenced by information about animal species, and not gender categories, on these questions.

Study 2

In Study 2, we tested whether guiding participants to view individuals' psychological properties as linked to category membership would lead them to predict greater levels of individual consistency. Participants were asked questions about pairs of either animals or human children that followed a similar format and referred to the same activities as those asked in Study 1. In Study 2, however, participants were given scenarios about two characters in which one character preferred one activity and the other character preferred the other activity. We hypothesized that when the pairs consisted of two individuals that shared category membership (e.g., two children of the same gender or two animals of the same species), the property would not be viewed as linked to category membership (as two members of the same category have two different preferences), and therefore, young children would again fail to predict consistency. In contrast, when participants are told about pairs consisting of members of different categories (e.g., two children of different genders or two animals of different species), we predicted that children would then view the property as category linked and would predict greater levels of individual consistency. We hypothesized that adults would readily predict consistency for all questions about preferences, regardless of category information. On the supplemental questions about choices, however, we hypothesized that they would be influenced by information about pair composition on questions about animal species but not human gender.

Method

Participants. Participants (n = 53, 23 male and 30 female) included 24 preschoolers (*M* age = 4 years 7 months; range = 3 years 11 months–5 years 8 months) and 29 adults (*M* age = 19 years 1 month; range = 17 years 9 months–22 years 7 months) drawn from the same population as those who participated in Study 1; no one participated in both studies.

Procedure. All participants were tested individually in a quiet office (located at either the children's schools or an on-campus laboratory) by the first author or by trained female undergraduate research assistants who were blind to study hypotheses. College students received course credit for their participation.

To limit the number of questions that each child was asked, participants were randomly assigned to receive questions about either animals or humans. Each condition included eight questions, which consisted of two blocks of four questions each, one block asked about pairs of individuals from the same category (i.e., same gender or same species) and the other block asked about pairs of individuals from different categories (i.e., different gender or different species). Order of presentation of the two blocks was counterbalanced across participants, and the questions within each block were asked in a separate random order for each participant. For adults, each block contained an additional four questions describing choices instead of preferences (see Appendix B). The same procedures as in Study 1 were used for assigning nonsense words to questions for each participant and for counterbalancing the order of nonsense words within each pair.

Questions followed the same structure and used the same properties as in Study 1, except that pairs of characters were described and none were given individual names (see Appendix B). For example, children heard: "Here are two children, a boy and a girl. A few days ago these children did two things, they went lexing and they went gorping. The boy liked lexing. The girl liked gorping. Today, the boy is doing those two things again. Again, the boy is going lexing and gorping. What will the boy like today? Will the boy like lexing, like last time, or will the boy like gorping?" After one question of each type, randomly selected in advance, participants were asked to recall the details of the story after they made their predictions, with the following questions, "Remind me … which one did [the boy] like the first time? And, which one did [the girl] like?" No participant had difficulty answering these control questions. Questions were accompanied by pictures of both characters and cards with the names of the activities printed on them. Pointing was used to aid comprehension. After the first set of preferences was described, the picture of the nontarget character was removed.

Results

We first present the analyses examining children's and adults' predictions about preferences, followed by supplemental analyses examining adults' predictions about choices. Preliminary analyses revealed that there were no main or interactive effects of participant gender or character gender; therefore, these variables were not included in analyses.

As shown in Figure 2, sign tests revealed that preschoolers predicted consistency at levels exceeding those expected by chance for questions about pairs of individuals from different categories (different gender: *M* = 0.71, *SD* = 0.32; different species: *M* = 0.85, *SD* = 0.27). In contrast, preschoolers predicted consistency less often than expected by chance on questions about same-gender pairs (*M* = 0.27, *SD* = 0.33) and at chance levels for same-species animal pairs (*M* = 0.60, *SD* = 0.34). Adults predicted consistency more often than expected by chance for all questions about preferences (same gender: *M* = 0.69, *SD* = 0.28; different gender: *M* = 0.75, *SD* = 0.27; same species: *M* = 0.83, *SD* = 0.28; different species: *M* = 0.89, *SD* = 0.23).

We further examined these data through a 2 (age: preschooler, adult) × 2 (condition: human

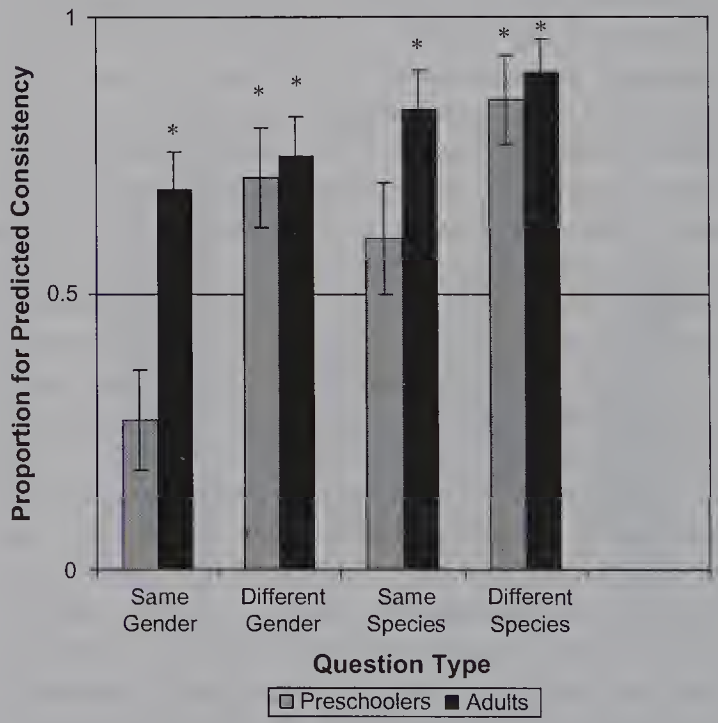

Figure 2. Proportion for predicted consistency by age and pair composition, Study 2.
Note. Error bars represent standard errors of the mean. Sign tests comparing the obtained proportions of predicted consistency to the proportion expected by chance.
$^*p < .05$.

children, animals) × 2 (pair composition: same category, different category) repeated measures ANOVA, with age and condition as between-subjects factors and pair composition as a within-subject factor. This analysis revealed main effects for pair composition, $F(1, 49) = 18.15$, $p < .001$, such that more consistency was predicted on questions about members of different categories; condition, $F(1, 49) = 8.86$, $p < .01$, such that more consistency was predicted for animals than people; and age, $F(1, 49) = 8.29$, $p < .001$, such that adults predicted consistency more often than did children. There was also a significant Pair Composition × Age interaction, $F(1, 49) = 8.48$, $p < .01$; see Figure 2. Planned contrasts revealed that preschoolers predicted consistency more often on questions involving pairs from different categories than on questions involving pairs from the same category ($p < .001$, $d = 1.20$), but adults' predictions did not differ depending on the composition of the pairs ($p > .5$). This pattern was identical and significant for questions about human and animal targets. Also, for same-category pairs, preschoolers predicted consistency less often than adults did ($p < .001$, $d = -1.04$), but for different-category pairs, they predicted consistency as often as did adults ($p > .3$).

Adults' predictions about choices. As hypothesized, adults predicted consistency more often than expected by chance only for questions describing animals of different species ($M = 0.75$, $SD = 0.28$, $p < .01$, sign test) and not for any other question type (same species: $M = 0.50$, $SD = 0.45$; different gender: $M = 0.45$, $SD = 0.26$; same gender: $M = 0.45$, $SD = 0.31$). Also as hypothesized, adults' predictions on questions about animals differed depending on the composition of the pair; adults predicted consistency more often on items describing different-species animals than on items describing same-species animals, $t(14) = 2.49$, $p < .05$, $d = .66$. In contrast, adults' predictions on questions about humans did not differ depending on the gender composition of the pair, $t(15) < .001$, *ns*

Discussion

In Study 2, we found support for the hypothesis that guiding preschoolers toward viewing individuals' preferences as linked to category membership leads them to predict greater individual consistency. Children predicted that preferences would remain consistent after learning that members of different categories had different preferences but not after learning that members of the same category had different preferences. We also documented that whereas adults' predictions about properties for which they have strong expectations of consistency (e.g., preferences) are not influenced by category information, they do attend to category information on questions about properties for which their expectations of consistency are less certain. Adults' concepts of different kinds of categories also appear to influence whether they view a category as relevant to individual consistency on these questions; adults were influenced only by information about animal species not by information about gender categories.

The results from adults' predictions about choices provide preliminary support for our hypothesis that categories are only used to predict individual consistency when the category is viewed as causally relevant to novel behaviors. We have not yet been able to document age-related changes in the use of gender and animal species on questions about the same psychological property, however, because adults predict preferences to be consistent so readily, and young children in this study were not asked questions about choices. We address this limitation in Study 3 by including a comparison group of 10-year-olds. We selected 10-year-olds for two reasons. First, previous research indicates that 10-year-olds predict consistency more often than do younger children, but we did not expect their predictions to be as stable as those of adults; therefore, we expected their predictions to be somewhat influenced by information about categories. Second, previous research indicates that by age 10, children have substantially refined their concepts of gender and view the influence of gender as relatively probabilistic and specific, as opposed to as deterministic and global (e.g., Berndt & Heller, 1986; Taylor, 1996; Taylor et al., in press). Therefore, we expected their inferences—like those of adults—to be influenced by information about animal species but not human gender. Comparing the responses of 10-year-olds with those of younger children will allow for a cleaner test of the hypothesis that beliefs about particular categories influence whether children appeal to category-based mechanisms.

Study 3

In Study 3, we further examined the developmental course of the results presented in Studies 1 and 2 by including a group of 10-year-olds. To maximize comparability between the two age groups, our younger participants in this study were drawn from kindergarten classes from the same elementary school attended by the 10-year-olds, who were drawn from fifth-grade classrooms. Thus, the participants in the younger age group of this study were slightly older than in Studies 1 and 2 but still within the age range of young children who are unlikely to engage in dispositional thinking on questions that provide limited evidence (e.g., Kalish, 2002).

We also made two small modifications designed to address the generality of our findings. First, we provided participants with information about what kinds of activities the characters engaged in. In Studies 1 and 2, participants were told relatively little information, for example, that characters had "gone lexing." They were left to infer that "lexing" is some sort of activity, but it could be a game, a chore, or any other type of activity. In Study 3, we examined whether children would use the same category-based strategies as they had in Study 2 when information about the types of activities that characters engaged in is explicitly given. For example, in these questions, children are told about boys and girls who played two games or bears and monkeys that climbed two kinds of trees. The options were still labeled using nonsense words (e.g., to refer the particular games or trees) in order to control for the influence of children's prior knowledge or experiences (e.g., their preferences for specific games). For example, children were told that characters played the "lex game and the gorp game."

Second, in Study 3, we expanded the types of psychological properties examined. In Study 2, children were asked questions about preferences only. Because preferences are an area that children frequently think about in terms of gender (e.g., games that girls like), it is possible that children's gender-based strategy is limited to questions about preferences. Alternately, because young children view gender as having a broad influence on psychological properties, they may apply this strategy more liberally. To distinguish between these possibilities, in Study 3, we included questions about both preferences and fears. We selected fears because older children tend to view fears as stable over time, whereas younger children may not (e.g., Kalish, 2002; Yuill, 1997).

Because Study 3 involved new sets of questions and new ages, we first conducted an initial pilot study following the same format as in Study 1. The goal of this pilot study was to confirm that 10-year-olds predicted consistency more often than 5-year-olds on questions about single individuals, using the new properties created for this study, when no information about categories is provided. After the pilot study demonstrated the expected age-related differences on our new items, we conducted the experimental study, in which participants were asked a series of questions about pairs of children and animals (similar to Study 2).

Method

Participants. Participants ($n = 55$; 26 male and 29 female) included 25 kindergarteners (M age = 5 years 7 months, range = 4 years 9 months–6 years 5 months) and 30 fifth graders (M age = 10 years 1 months, range = 9 years 2 months–11 years 4 months) recruited from a single public elementary school in a Midwestern university town. Eleven of the kindergartners and 15 of the fifth graders were assigned to the pilot study, and the rest were assigned to the main study (described below).

Procedures. Participants were tested in a quiet office at their elementary school by either the first author or trained female undergraduate research assistants who were blind to study hypotheses. In both the pilot study and the main study, participants were asked a total of 16 questions (8 about animal pairs and 8 about human pairs). Questions were blocked by character type, and order of presentation of these blocks was counterbalanced across participants; kindergarteners completed the blocks in two sessions, approximately 1 week apart; fifth graders completed the study in a single session. Within each block, questions were also blocked by pair type (same category or different category), with order of these blocks also counterbalanced across participants. Within each block, questions were presented in a separate random order for each participant. Procedures for counterbalancing nonsense words were the same as in previous studies.

Pilot study. In the pilot study, participants were asked questions about individual actors—eight human characters and eight animal characters—which followed the same structure as the questions used in Study 1 but referred to the new properties developed for this study. Half of the questions asked about preferences and half asked about fears, such that there were four questions of each of four types (four animal preferences, four animal fears, four human preferences, and four human fears; see Appendix C). Results from this pilot study indicated that the questions using the new properties elicited the expected age-related findings. Specifically, kindergarteners did not predict consistency more often than expected by chance on any questions (human children: $M = 0.36$, $SD = 0.44$; animals: $M = 0.30$, $SD = 0.43$; $p > .34$, sign tests), whereas fifth graders predicted consistency more often than expected by chance for both kinds of characters (human children: $M = 0.70$, $SD = 0.33$; animals: $M = 0.70$, $SD = 0.31$; $p < .05$, sign tests). Also, fifth graders predicted consistency more often than did kindergarteners on questions about both humans, $t(24) = 2.22$, $p < .05$, $d = .87$, and animals, $t(24) = 2.78$, $p < .05$,

d = 1.08. There were no effects associated with property type (preference or fear).

The questions asked in this pilot study were similar in design and purpose to those asked in Study 1, with three changes: (a) the properties were modified as described above, (b) the younger participants were slightly older than in Study 1, and (c) category labels were used to refer to the characters in the question (e.g., "This is a girl") instead of proper names (e.g., "This is Molly"). Despite these changes, the proportion of questions on which kindergarteners predicted consistency did not differ significantly from the proportion of questions on which preschoolers in Study 1 predicted consistency, on questions about human children, $t(23) = .73$, *ns*, or animals, $t(23) = .82$, *ns*. Based on these findings, we developed the questions for the main study using the new property descriptions.

Main study. In the main study, participants were asked eight questions about animals (four same-species pairs and four different-species pairs) and eight questions about children (four same-gender pairs and four different-gender pairs). Thus, there were four questions of each of four types (see Appendix D). Procedures were similar to Study 2 and materials included the same pictures of the story characters, as well as cards containing the names of the target activities.

Results

In the main study, we first compared the proportion of questions on which participants predicted that characters would behave consistently to the number expected by chance for each type of question, followed by repeated measures ANOVAs. Preliminary analyses revealed that there were no main or interactive effects of participant gender or character gender; therefore, this variable was not considered in analyses. Also, there were no differences between preferences and fears for either age group; in no analysis did the main or interactive effect of property type (preference or fear) approach significance (all $ps > .4$). Therefore, we collapsed across this distinction.

As shown in Figure 3, sign tests revealed that kindergarteners predicted consistency more often than expected by chance on items involving different category members for questions about both human gender ($M = 0.80$, $SD = 0.33$) and animals ($M = 0.73$, $SD = 0.40$) but not for questions involving same-category pairs (same gender: $M = 0.41$, $SD = 0.35$; same species: $M = 0.43$, $SD = 0.36$). Fifth graders predicted consistency more often than expected by chance for items involving different animal species only ($M = 0.75$, $SD = 0.27$) and not for items involving same-species animals ($M = 0.63$, $SD = 0.39$), same-gender children ($M = 0.68$, $SD = 0.35$), or different-gender children ($M = 0.62$, $SD = 0.38$).

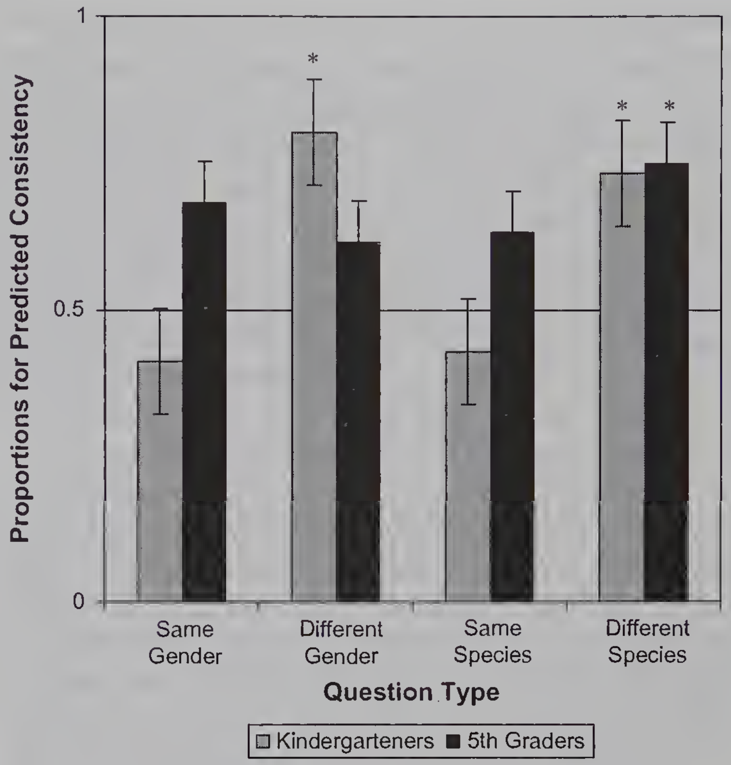

Figure 3. Proportion for predicted consistency by age and pair composition, Study 3.
Note. Error bars represent standard errors of the mean. Sign tests comparing the obtained proportions of predicted consistency to the proportion expected by chance.
$*p < .05$.

We further examined these data through a 2 (target: animal, human) × 2 (pair composition: same category, different category) × 2 (age: kindergarten, fifth grade) repeated measures ANOVA, with target and pair as within-subjects factors and age as a between-subjects factor (see Figure 3). This analysis revealed a main effect of pair composition, $F(1, 27) = 16.64$, $p < .001$, and a significant interaction between pair composition and age, $F(1, 27) = 12.48$, $p < .01$. Planned contrasts revealed that kindergartners predicted consistency more often on questions about different-category members than on questions about same-category members, for both human and animal characters ($p < .001$; gender, $d = 1.15$; animal, $d = .79$). Although the three-way interaction among target, pair composition, and age failed to reach significance ($p = .1$), for fifth graders, as hypothesized, pair composition did not influence responses on items about gender: Predictions about same-gender and different-gender pairs did not differ ($p > .3$). However, pair composition did influence responses on items about animals: Predictions of consistency were made significantly more often about different-species pairs than about same-species pairs, $t(14) = 2.43$, $p < .05$, $d = .35$.

Discussion

In Study 3, we replicated the findings from Studies 1 and 2 for younger children and extended these findings to questions about fears. When presented with questions involving individual human children or animals, kindergartners did not expect the characters to have consistent preferences or fears over time (as demonstrated in the pilot study). When presented with pairs of children or animals, however, kindergartners expected characters to have consistent preferences and fears only when they were told that members of different categories had different properties.

In contrast, fifth graders generally expected humans and animals to have consistent preferences and fears, as evidenced in the pilot study. Also as hypothesized, fifth graders predicted consistency more often on questions about different-species animals than on questions about same-species animals but did not differentiate between questions about same-gender and different-gender pairs. These findings are consistent with prior work demonstrating that older children view gender as less influential for behavior than do younger children (e.g., Berndt & Heller, 1986; Taylor, 1996). These findings, as well as the findings from Study 2, suggest that developmental changes in how gender influences predictions of consistency on these questions relate to changes in children's gender concepts not to a general move away from viewing category information as relevant to individual consistency.

Surprisingly, fifth graders demonstrated chance-level responding on all questions in the main study, except for questions involving pairs of different animals. Thus, learning that pairs of children had different preferences and fears may have led fifth graders away from predicting consistency. Although the predictions of fifth graders did not differ from chance in the main study, they did still predict consistency more often than kindergarteners. Nevertheless, it is somewhat surprising that fifth graders' predictions on these questions were not above chance, as they are well within the age range of children that have been shown to engage in dispositional reasoning in other studies (e.g., Kalish, 2002).

Children's spontaneous explanations that accompanied these questions provide some insight into this unexpected pattern. Participants frequently mentioned various social learning mechanisms in explaining their responses. For example, children suggested that characters might "learn to like it from their friend" or "become afraid of it because their partner did" (explanations fitting this interpretation were given at least once by 8 of 14 fifth graders in this condition). Thus, children hypothesized that social interactions between the characters might influence the tendency to try new things or remain consistent. Importantly, this process was not influenced by the gender composition of the pair, supporting the hypothesis that fifth graders would not view gender as influencing the consistency of these psychological properties. It is also possible, given children's explanations, that their beliefs about the social context presented in the study questions somehow guided them away from viewing gender as relevant. Species information, however, did influence this pattern, as described above. Thus, although children posited social interactions that would lead the pairs of children and animals to influence each other, they did not expect such interactions to operate across species boundaries (although they did expect them to operate across gender categories). Overall, these findings support the prediction that, with age, children develop more differentiated concepts of animal species and gender categories.

Study 4

Study 4 was a control study, which was designed to test whether young children appeal to category-based mechanisms only when the category information that is presented refers to meaningful differences between people. In Studies 2 and 3, young children reliably predicted consistency on questions involving both different-gender humans and different-species animals. One possibility is that young children will appeal to *any* observable difference between actors to make predictions about consistency, even if the distinction is relatively unlikely to influence the behavior of interest. From this perspective, the more children are guided to focus on the differences between two characters, the more likely they may be to infer stable individual differences. If this were the case, then young children's responses on our previous studies would not be indicative of their beliefs about the causal power of gender or species categories per se and would not represent a theory-driven category-based approach to social reasoning. Alternately, if children use gender categories, but not relatively more trivial differences between people, to predict consistency, then the pattern of findings documented in our earlier studies may be interpreted as reflecting the conceptual status of gender categories and animal species. To distinguish between these two possibilities, we compared children's reasoning about pairs of different-gender children and pairs of children who differ on another easily observable (but less meaningful) dimension, in this case, shirt color. We selected shirt color because it is easy for young children to track visually, amenable to labeling, and has been used in other studies designed to compare reasoning about deep and relatively superficial categories (Solomon, 2002).

Method

Participants. Participants included 12 preschoolers (5 male and 7 female; *M* age = 4 years 8 months, range = 4 years 1 month–5 years 7 months) recruited from the same population areas as children who participated in Studies 1 and 2. None had participated in an earlier study.

Procedure. Children were tested individually, following the procedures used in previous studies. All children were asked a series of eight questions: four about different-gender pairs and four about pairs of children (of the same gender) who wore different-color shirts. Items were blocked by pair type (gender or shirt color), and order of presentation of the blocks was counterbalanced across participants. Within the blocks, items were presented in a separate random order for each participant. The questions about gender began, "See these two children? This one is a boy. This one is a girl," and then were identical to the different-gender pair questions from Study 2. The questions about shirt color began "See these two children? This one is wearing a yellow shirt. This one is wearing a green shirt," and then followed the same structure as the other questions (see Appendix E). As in previous studies, children were presented with simple pictures of the story characters, as well as with small cards with the names of the nonsense activities printed on them, and pointing was used to aid comprehension. New pictures were used for this experiment, so that we could control shirt color (for different-gender pairs, the children wore the same-color shirt; for different-shirt-color pairs, children were of the same gender, but one wore a yellow shirt and one wore a green shirt). As in previous studies, order of presentation of each nonsense word within a pair and the character's selected preference were counterbalanced across participants and the pairs of nonsense words circulated across items.

Results

Consistent with previous studies, preschoolers predicted that characters' preferences would remain consistent more often than expected by chance when they were told about different-gender pairs ($M = 0.73$, $SD = 0.31$, $p < .05$, sign test). As hypothesized, however, they did not predict that preferences would be consistent when they were told about pairs of children wearing different-color shirts; in fact, they predicted that preferences would be consistent marginally less often than expected by chance ($M = 0.27$, $SD = 0.39$, $p = .09$, sign test), which was similar to preschoolers' performance on questions about same-gender pairs in Study 2. Children predicted consistency more often on questions about gender pairs than on questions about shirt-color pairs, $t(11) = 5.01$, $p < .001$, $d = 1.53$.

Discussion

In this control study, we documented that preschoolers apply a category-based strategy only when the individual differences that are presented relate to meaningful categories (i.e., gender) but not when they relate to more trivial differences (i.e., shirt color). These findings support our interpretation that individuals appeal only to categories that they view as having an important causal influence on behavior to predict consistency and suggest that preschoolers appeal to categories in a strategic manner to predict the future.

General Discussion

We examined whether individuals rely on category information to predict individual behavior. We found that preschoolers, older children, and adults all rely on such a process to guide their social reasoning. We also found, however, that there are age differences in how commonly participants engaged in category-based reasoning, as well as in which kinds of categories individuals found informative for reasoning about these items.

We found robust evidence for a category-based approach to reasoning about individual consistency among preschoolers and kindergarteners. When young children were told that a single individual experienced two options and had a preference for or was afraid of one of them, they were no more likely to predict that those responses would be consistent over time than expected by chance, congruent with prior work (e.g., Kalish, 2002). When young children were told that two characters from different salient categories had unique responses (e.g., a boy liked one option, whereas a girl liked the other), however, they predicted that psychological responses would be consistent over time more often than expected by chance and as often as adults did. We found evidence for increased predictions of consistency only when the two characters differed in terms of membership in an important category; young children did not predict consistency when they were told about the unique responses of two characters that shared category membership (e.g., two girls), even if the two characters differed in some other observable manner (e.g., shirt color).

Young Children's Category-Based Reasoning

Why do preschoolers predict consistency when they learn that members of different categories have different properties? It is well documented that young children view membership in certain categories as fundamental to identity and as determining a wide range of behaviors (Gelman, 2003). Much of this research has focused on children's beliefs about animal species and has demonstrated that young children make a broad range of inferences about animals' properties based on species information alone (Gelman & Markman, 1986; Gelman & Wellman, 1991; Sousa, Atran, & Medin, 2002; Waxman, Medin, & Ross, 2007). As described by Gelman, (2003), species categories take on this inductive potential because children view category membership as tied to the presence of a category "essence," or a nonobvious internal entity that exists in every category member and causes category membership and the development of category-linked properties. Thus, the development of category properties is viewed as causally related to category membership.

A number of studies indicate that children also perceive membership in some social categories as resulting from the presence of a category essence (Astuti, Solomon, & Carey, 2004; Diesendruck & haLevi, 2006; Hirschfeld, 1996; Taylor, 1996). Preschoolers treat gender categories in particular as having high inductive potential and as causally determining behavior. For example, preschoolers expect members of the same-gender category to share novel properties even in the face of contradictory perceptual or environmental information (Gelman et al., 1986; Taylor, 1996). Thus, preschoolers appear to use gender categories and animal species information in a similar manner in inductive reasoning, treating them both as indicating membership in natural kinds (Rothbart & Taylor, 1992).

Information about category membership, whether regarding animal species or human gender, presents young children with powerful causal explanations for behavior. When confronted with the question of whether a particular behavior is likely to be consistent over time, the belief that a behavior is causally related to category membership provides a strong reason to predict consistency. We propose that because categories provide such important explanatory information, young children are sensitive to detecting category-linked distributions. In the present studies, they formed expectations that a behavior was tied to gender after a single piece of evidence. Behaviors were never labeled as "for boys" or "for girls," children made this inference on the basis of information about only two individuals.

Developmental Changes in Category-Based Reasoning

Adults and older children (fifth grade) also relied on information about categories to guide their inferences about consistency, but only on questions involving animal species, and for adults, only on questions about particular psychological properties. We will discuss two aspects of the development of social cognition that we believe account for these age-related findings, one related to the increased salience of dispositionism as a lay theory for explaining behavior, and the other related to changing beliefs about gender.

Dispositionism. Kalish (2002) suggests that dispositions, or internal stable individual differences, are not salient causal mechanisms within young children's theories of behavior. Although previous work suggests that preschoolers have some capacity to engage in dispositional thinking (e.g., Heyman & Gelman, 2000), on problems about individual consistency they appear to require more or different kinds of evidence than older children and adults before they will view a given behavior as good evidence on which to base an inference of future consistency.

This interpretation is consistent with findings from cross-cultural research indicating increasing cultural divergence in social attribution with age. These cross-cultural findings suggest that social attribution is, at least in part, the result of an extended process of socialization (Miller, 1984, 1986). Wellman and Miller (2006) summarize this body of literature and suggest that although there are some cross-cultural commonalities in young children's understanding of people and behavior (e.g., viewing people as active and intentional agents), the specifics of children's naïve theories of psychology, including which factors they view as salient and powerful behavioral motivators, vary cross culturally. Among adults as well, some aspects of social attribution appear to be common across cultures (e.g., viewing individuals as active in initiating their own behavior), but individuals in different cultural contexts appear to differ in the extent to which they also attribute a potent causal role to the environment (Choi et al., 1999; Morris & Peng, 1994; Norenzayan, Choi, & Nisbett, 2002). Thus, attributing a primary causal role to individual dispositions appears to be the result of a process of socialization, interacting with a probably universal tendency to view humans as intentional. From this perspective, it is not expected that preschoolers would share the same conceptual framework for explaining and predicting behavior as the adults in their environment, as much of socialization is yet to be completed (Wellman & Miller, 2006). Thus, the increasing salience of dispositionism with age in the present context may contribute to our finding that older children and adults relied on a category-based strategy less often than did younger children.

Gender concepts. A second developmental process that may contribute to the present findings relates to developmental changes in concepts of different kinds of categories. Young children reasoned about animal species and human gender in a similar manner, regardless of whether this variable was manipulated within or between participants, suggesting that young children attribute a similar causal role to both kinds of categories. Young children's relatively strict concepts of gender have been suggested to relate to a general tendency to focus on within-category similarity and between-category differences and to ignore within-category variability (Gelman, 2003; Gelman & Coley, 1991; Maccoby, 1988). Their approach to gender may also relate to specific beliefs about *how* gender influences behavior. For example, previous work suggests that preschoolers view engaging in gender-stereotyped behaviors as somewhat automatic, or as necessary for fulfilling moral or social obligations, as opposed to as subject to environmental or intentional control (Levy, Taylor, & Gelman, 1995; Taylor et al., in press).

In contrast, fifth graders' and adults' reasoning appeared to reflect more differentiated concepts of animal species and human gender; they were influenced by category information about animal species only. Prior work has suggested that, over time, individuals come to view gender as influencing a narrower set of properties, as well as to view the influence of gender on behavior as probabilistic and dependent on environmental pressure and personal agency (Berndt & Heller, 1986; Taylor, 1996). Although adults and older children often hold some strict stereotypes about gender, these may be more specific than the theories held by young children. With age, individuals' concepts of gender focus on differences in particular areas, whereas younger children expect more general differences (Maccoby, 1988). Thus, we propose that developmental changes in theories about gender also contribute to our age-related findings.

We have indicated that because young children view gender categories as such strong predictors of behavior, they are willing to infer a gender-linked cause for behavior after one example of a gender-linked pattern. In contrast, the presented evidence was not sufficient to warrant such an interpretation by older children or adults. We suspect, however, that older children and adults would rely on gender if they were presented with a greater amount of gender-linked information (e.g., questions involving stereotypical properties or more examples of gender-linked patterns). In future research, it would be interesting to compare how much gender-linked information preschoolers, older children, and adults require before they view novel behaviors as related to gender.

Limitations and Future Directions

A direction for future research suggested by these findings stems from the fact that the information about past experiences provided to participants in the present experiments was relatively minimal, as was the information provided about categories. In the present work, we found that when both of these sources of information are minimal (e.g., one example of a prior behavior and one example of a category-linked distribution), preschoolers relied on category-linked information but not dispositions to guide their inferences. One limitation of this approach, however, is that all the activities referred to in the present research were novel. Although using novel activities in this context was useful for experimental control, it is certainly possible that preschoolers will infer dispositions based on single acts if they are able to apply their knowledge about particular activities (e.g., they may view some activities, such as liking brussel sprouts, as distinct enough as to warrant dispositional reasoning).

Also, because the information provided was limited, we cannot determine from the present research when children might rely on a category-based strategy in more realistic contexts. Based on prior work, we suspect that if more information about previous behavior was provided, preschoolers may be more likely to view the behavior as linked to a disposition (e.g., Boseovski & Lee, 2006). Providing more information about gender, however, should also lead to heightened reliance on gender categories to predict behavior. In future research, it would be interesting to examine how young children integrate information about past experiences and social categories when both sources of information are highly salient. Using realistic examples of behavior, Berndt and Heller (1986) found that young children preferred to base inferences about the future on gender stereotypes rather than on past behavior; however, children in this study were also given relatively limited information (see also Biernat, 1991). Thus, this remains an important area for future work.

These findings are also limited by the cultural context in which we conducted this research. Specifically, the age-related decline in the influence of gender-linked information documented in the present studies must be interpreted within the context of the present sample. All the data for these experiments were collected in a relatively liberal university town. Thus, it is possible that other cultural contexts support the maintenance of strict gender concepts throughout development. Interestingly, even in the relatively liberal cultural context sampled in the present work, we still found that young children hold relatively strong views regarding the influence of gender on behavior and reasoned about gender categories in a comparable manner to how they reasoned about animal species. In less egalitarian contexts, older children and even adults may continue to rely on gender to guide inferences about individual consistency when limited evidence is available. We interpret the present findings as indicating that whether individuals rely on a category-based strategy when making social inferences depends on the causal power attributed to the category for determining a wide range of behaviors. Whether gender is viewed in this manner should depend on age (as documented in the present work) as well as context (e.g., Crouter, Whiteman, & McHale, 2007).

In future research, it would also be interesting to examine how individuals reason about other social categories. We demonstrated that preschoolers appeal to membership in gender categories, but not more trivial differences based on shirt color, to guide their inferences. Based on our framework, we would expect that other social categories that individuals perceive as causal motivators of behavior to be used in a similar manner. For example, prior work suggests that young children attribute causal influence to categories based on race (Hirschfeld, 1996) and ethnicity (Astuti et al., 2004; Diesendruck & haLevi, 2006). Thus, we would expect children (and adults) to rely on these categories and others as well, to the extent that they view the categories as having a strong influence on a wide range of known and unknown behaviors.

In sum, these results inform two aspects of the development of social cognition, children's understanding of the mechanisms leading to individual consistency and the ways in which concepts of social categories influence children's expectations about the social world. These findings extend knowledge of how young children make sense of the social world, by pointing toward cues that preschoolers use when determining which behaviors are likely to be engaged in consistently over time. The present findings also document the importance of considering how young children's emerging theories of behavior and of social groups operate together to inform their explanations and predictions about the social world.

Sample Items Study 1

Human preference	Here is Megan. A few days ago, Megan did two things—Megan went famming and Megan went lopping. Megan liked famming. Today, Megan is doing two things again. Again, Megan is going famming and lopping. What will Megan like today? Will Megan like famming, like last time, or will Megan like lopping?
Human choice	Here is Billy. A few days ago, Billy had a choice. Billy could either go rilling or Billy could go taffing. Billy went rilling. Today, Billy has a choice again. Again, Billy can either go rilling or taffing. What will Billy do today? Will Billy go rilling, like last time, or will Billy go taffing?
Animal preference	Here is Buttercup. A few days ago, Buttercup did two things. Buttercup went soting and Buttercup went tabing. Buttercup liked soting. Today, Buttercup is doing two things again. Again, Buttercup is going soting and tabing. What will Buttercup like today? Will Buttercup like soting, like last time, or will Buttercup like tabing?
Animal choice	Here is Torty. A few days ago Torty had a choice. Torty could either go vanning or Torty could go jerning. Torty went vanning. Today Torty has a choice again. Again, Torty can either go vanning or jerning. What will Torty do today? Will Torty go vanning, like last time, or will Torty go jerning?
Nonsense words	Pipping, famming, lexing, zazzing, lopping, gorping, tooping, fepping, jerning, flecking, daxing, vanning, spouding, soting, heesting, bemming, tabbing, sugging, pagging, sudding, shaining, flooming, molling, risting, fulfing, thaying, blicking, plizzing, rilling, hepping, taffing, pomming

Appendix B

Sample Items Study 2

Same-gender pair	Here are two boys. A few days ago, they did two things; they went bemming and they went spouding. This boy liked bemming. This boy liked spouding. Today, this boy is doing two things again. Again, this boy is going bemming and spouding. What will this boy like today? Will this boy like bemming, like last time, or will this boy like spouding?
Different-gender pair	Here are two children, a girl and a boy. A few days ago they did two things; they went shaining and they went risting. The girl liked shaining. The boy liked risting. Today, the girl is doing two things again. Again, the girl is going shaining and risting. What will the girl like today? Will the girl like shaining, like last time, or will the girl like risting?
Same-species pair	Here are two pigs. A few days ago, they did two things; they went flooming and they went pagging. This pig liked flooming. This pig liked pagging. Today, this pig is doing two things again. Again, this pig is going flooming and pagging. What will this pig like today? Will this pig like flooming, like last time, or will this pig like pagging?
Different-species pair	Here are two animals, a lion and a bear. A few days ago they did two things, they went thaying and they went plizzing. The lion liked thaying. The bear liked plizzing. Today, the lion is doing two things again. Again, the lion is going thaying and plizzing. What will the lion like today? Will the lion like thaying, like last time, or will the lion like plizzing?
Sample choice question (asked to adults only)	Here are two children, a girl and a boy. A few days ago they had a choice. They could either go shaining, or they could go risting. The girl went shaining. The boy went risting. Today, the girl has a choice again. Again, the girl can either go shaining or risting. What will the girl do today? Will the girl go shaining, like last time, or will the girl go risting?

Appendix C
Sample Items Study 3, Pilot Study

Human preference	Here is a boy. A few days ago, this boy had two things for a snack, a fep and a dax. This boy liked the fep. Today, this boy is having two things for a snack again. Again, this boy is having a fep and a dax. What will this boy like today? Will this boy like the fep, like last time, or will this boy like the dax?
Human fear	Here is a girl. A few days ago, this girl saw two animals, a toop and a fleck. This girl was afraid of the toop. Today, this girl sees two animals again. Again, this girl sees a toop and a fleck. What will this girl be afraid of today? Will this girl be afraid of the toop, like last time, or will this girl be afraid of the fleck?
Animal preference	Here is a monkey. A few days ago, this monkey climbed two kinds of trees, floom trees and pag trees. This monkey liked climbing floom trees. Today, this monkey is climbing trees again. Again, this monkey is climbing floom trees and pag trees. What will this monkey like climbing today? Will this monkey like floom trees, like last time, or will this monkey like pag trees?
Animal fear	Here is a mouse. A few days ago, this mouse saw two animals, a lex and a gorp. This mouse was afraid of the lex. Today, this mouse sees two animals again. Again, this mouse sees a lex and a gorp. What will this mouse be afraid of today? Will this mouse be afraid of the lex, like last time, or will this mouse be afraid of the gorp?

Stability and Change of Moral Disengagement and Its Impact on Aggression and Violence in Late Adolescence

Marinella Paciello, Roberta Fida, Carlo Tramontano, Catia Lupinetti, and
Gian Vittorio Caprara
Sapienza University of Rome

Stability and change of moral disengagement were examined in a sample of 366 adolescents from ages 14 to 20 years. Four developmental trajectories were identified: (a) nondisengaged group that started with initially low levels followed by an important decline, (b) normative group that started with initially moderate levels followed by a decline, (c) later desister group that started with initially high-medium levels followed by an increase from 14 to 16 years and an even steeper decline from 16 to 20 years, and (d) chronic group that started with and maintained medium-high levels. The results attest that adolescents who maintained higher levels of moral disengagement were more likely to show frequent aggressive and violent acts in late adolescence.

Among the mechanisms conducive to aggression, moral standards exert a notable influence in dictating when it may be legitimate to resort to behavior that may hurt other people and when, on the contrary, one has to refrain from detrimental conduct (Bandura, 1986, 1991, 2001). People are active agents who pursue their goals in accordance with personal standards that serve as guides and deterrents for action through self-reactive anticipatory evaluations. People monitor their conduct and the conditions under which it occurs, judging their actions in relation to their moral standards and perceived circumstances, and regulate their actions by anticipating the consequences they would apply to themselves. People do things that give them satisfaction and refrain from behaviors that bring self-censure. Anticipatory self-pride and self-blame are suggested to be human mind self-regulatory capacities that keep behavior in line with personal standards. Yet, this does not exclude the possibility that people, after having adopted personal standards and despite being morally committed to ethical principles, may enact behaviors that violate those standards, while continuing to profess those principles and avoiding feelings of conflict, guilt, or remorse. The chronicles of recent atrocities attest to the fact that even considerate people may become engaged in inhumane behavior without experiencing any moral concern or discomfort (Bandura, 1999, 2004; Zimbardo, 1995, 2004).

In this regard, Bandura's (1986) social cognitive theory provides a theory of *moral agency* that supplies the conceptual apparatus that is needed to clarify the mechanisms by which people come to live in accordance with moral standards as well as the mechanisms that allow a kind of divorce between moral thought and moral actions (Bandura, 1991; Bandura, Barbaranelli, Caprara, & Pastorelli, 1996). In particular, Bandura (1986, 1991) has introduced the construct of moral disengagement to explain the determinants and mechanisms governing aggressive behaviors. Moral disengagement refers to individual's tendency to use mechanisms conducive to a selective disengagement of moral censure. This is achieved by reconstructing behavior, obscuring causal agency, misrepresenting injurious consequences, and blaming victims. These mechanisms allow individuals to engage in self-serving behavior that is in contrast with their moral principles, while continuing to advocate those principles and without incurring self-evaluative emotional reactions such as guilt. It is likely that these mechanisms become crystallized over time when dealing with transgressions in the pursuit of self-interest. Indeed, a previous study found that moral disengagement to be positively correlated with self-enhancement and negatively correlated with self-transcendence (Caprara & Capanna, 2005).

The focus of the present study is to examine the stability and change of moral disengagement both at

a population level and at an interindividual level as well as explore the extent to which different developmental pathways are associated with different aggressive and violent outcomes over the course of adolescence. Over the past few decades, different cognitive theories have examined moral development and the relation among moral thinking, social behaviors, and social context (Bandura, 1986; Crick & Dodge, 1994; Dodge & Crick, 1990; Gibbs, Potter, Barriga, & Liau, 1996; Huesmann, 1988, 1998; Kohlberg, 1969; Turiel, 1978, 1983). Furthermore, extensive knowledge has been accumulated on the development of processes related to moral self-regulation, such as the construction of moral standards, the formation of moral judgments, and the exercise of self-influence through emotional self-reactions (Bandura, 1991; Eisenberg, 2000; Killen & Smetana, 2006; Tangney, Stuewig, & Mashek, 2007; Turiel, 2006). According to social cognitive theory and adopting a developmental approach, we focus on self-exonerative mechanisms that exert a crucial role in attenuating the links between moral thought and moral actions. These mechanisms have been overlooked in the examination of moral development. To our knowledge, this is the first study that longitudinally maps individual differences in moral disengagement over the course of adolescence.

The present study focused on the adolescent transition because various manifestations of aggression may dramatically change throughout childhood, adolescence, and early adulthood, and these changes are not the same for all individuals (Brame, Nagin, & Tremblay, 2001; Loeber & Stouthamer-Loeber, 1998; Moffitt, 1993; Sampson & Laub, 2003; Tremblay, 2000). Most adolescents adopt antisocial behavior patterns but a large part abandon them in adulthood and only a small percentage become deeply and chronically engaged in risky aggressive and violent behaviors (Loeber, 1991; Loeber & Hay, 1997; Tremblay, 2000). We believe that moral disengagement can be crucial in explaining mechanisms conducive to chronic engagement in aggressive and violent behavior (Bandura, 1999; Bandura, Caprara, Barbaranelli, Pastorelli, & Regalia, 2001; Bandura et al., 1996; Zimbardo, 2004, 2006).

Moral Disengagement

Over the course of development, the adoption of moral standards attests that the property of human mind is guided from within in accordance with principles that derive from one's own and others' experiences and that, in various ways, are at the core of social life. Individuals' increasing self-regulatory capacities and the change from external to autonomy regulation make adolescence a period particularly sensitive for the study of moral functioning. During adolescence, the development of metacognitive abilities promotes the internalization of moral principles, and ultimately, the development of one's own moral identity and agency (Bergman, 2002; Blasi, 1984; Carlo, Eisenberg, & Knight, 1992; Hardy & Carlo, 2005; Helwig & Turiel, 2003; Kohlberg & Candee, 1984; Krettenauer, 2004; Swanson & Hill, 1993). Once formed, moral standards dictate the goals to be pursued and the actions from which to refrain and exert their influence over behavior through anticipated positive and negative self-evaluative reactions. Although self-sanctions carrying feelings of guilt are associated with actions that violate individual moral standards, positive reactions carrying pride, and self-worth are associated with actions that promote those moral standards (Bandura, 1991; Bandura & Walters, 1959; Elkin & Westley, 1955; Emmons & Diener, 1986). Self-sanctions exert an important influence in refraining individual's detrimental conduct particularly when one's interest is at stake, and detrimental conduct may be instrumental in the pursuit of specific goals. However, the adoption of moral abstract principles, although necessary, is not always sufficient to refrain from detrimental conduct. Through moral disengagement, self-sanctions can be deactivated and affective self-evaluative reactions are avoided, permitting different types of detrimental conduct while saving the same moral standards.

In the social cognitive theory of moral agency, there are four major points at which self-sanction can be disengaged from detrimental conduct and eight mechanisms that have been corroborated experimentally, through which moral disengagement operates (Bandura, 1991). Different disengagement practices may focus on the *behavior*, on the sense of *personal responsibility*, on the *outcomes* of behavior, and on the *recipients* of behavior. Thus, the first set of disengagement practices—focusing on behaviors—operates on the cognitive construal of the behavior itself. It includes *moral justification*, *euphemistic language*, and *advantageous comparison*. By moral justification, detrimental conduct is made personally and socially acceptable (Kelman & Hamilton, 1989; Rapoport & Alexander, 1982; Reich, 1990; Sanford & Comstock, 1971). A lot of aggressive behavior gets justified in the name of protecting honor and reputation (Cohen & Nisbett, 1994). Euphemistic language provides a convenient way of masking immoral activities conferring a respectable status upon them (Bollinger, 1982; Diener, Dineen, Endresen, Beaman, & Fraser, 1975; Lutz, 1987). People behave much more aggressively when assaulting a person is given a sanitized label than when it is called aggression. By advantageous comparison, detrimental conduct can lose its repugnancy by comparing it with more flagrant inhumanities (Bandura, 1991). The more flagrant the contrasted activities, the more likely it is that one's own injurious conduct will appear trifling or even benevolent. The second set of disengagement mechanisms—focusing on personal responsibility—operates by obscuring, minimizing, or disclaiming the agentic role in the harm that one causes. It includes *displacement of responsibility* and *diffusion of responsibility* by which people view their actions as ordered by the social pressures of others rather than as something for which they are personally responsible (Bandura, Underwood, & Fromson, 1975; Diener, 1977; Milgram, 1974; Zimbardo, 1995). People are willing to behave in ways they normally repudiate if a legitimate authority accepts responsibility for the effects of their actions and if responsibility can be diffused (when everyone is responsible, no one really feels responsible). The third set of disengagement mechanisms—focusing on outcomes—avoids self-deterring reactions by *disregarding* or *distorting the consequences of action*. When people are involved in activities harmful to others for personal gain or because of social inducements, they avoid facing the harm they cause or they minimize it (Klass, 1978). They readily recall prior information given to them about the potential benefits of the behavior, but are less able to remember its harmful effects (Brock & Buss, 1962, 1964). In addition to selective inattention and cognitive distortion of effects, the misrepresentation may involve active efforts to discredit evidence of the harm they cause. The final set of disengagement practices focusing on the recipients of detrimental acts includes *dehumanization* and *attribution of blame*. Dehumanization divests people of human qualities or attributes bestial qualities to them. Once dehumanized, they are no longer viewed as persons with feelings, hopes, and concerns but as subhuman objects (Haritos-Fatouros, 1988; Keen, 1986; Kelman, 1973). It is difficult to mistreat humanized persons without risking personal distress and self-censure. By attribution of blame, people view themselves as faultless victims driven to injurious conduct by forcible provocation (Crick & Dodge, 1994; Darley, Klosson, & Zanna, 1978; Ferguson & Rule, 1983; Weiner, 1986). Punitive conduct thus becomes a justifiable defensive reaction to instigations.

A number of findings have shown that the above eight mechanisms can be traced back to a common latent variable that makes people more or less inclined to use mechanisms of moral disengagement (Bandura et al., 1996, 2001; Caprara, Bandura, Barbaranelli, & Vicino, 1996; Pelton, Gound, Forehand, & Brody, 2004). Thus, the proneness to moral disengagement is assessed by the processes through which it is presumed to operate. Appropriate assessment measures have already been developed in order to investigate how the full set of moral disengagement mechanisms operate in concert (Bandura, 2004; Bandura et al., 1996; Caprara et al., 1996).

A large body of research has demonstrated the disinhibitory power of moral disengagement in fostering aggressive behavior (Andrus, 1969; Bandura, 1990, 2006; Kelman & Hamilton, 1989; Rapoport & Alexander, 1982; Reich, 1990). In adolescence, different studies have shown strong associations between proneness to moral disengagement and various measures of aggression and violence, as well as other forms of antisocial conduct and bullying (Bandura, Caprara, & Zsolnai, 2000; Bandura et al., 1996, 2001; Caprara et al., 1996; Gini, 2006; Menesini et al., 2003). Longitudinal studies have found that high levels of moral disengagement predict levels of violence, theft, and other forms of antisocial conduct (Bandura et al., 2001; Elliott & Rhinehart, 1995; Pepler, Jiang, Craig, & Connolly, 2008). On the one hand, high moral disengagers tend to be more irritable, more prone to vengeful rumination, more inclined toward physical and verbal aggression, and more frequently involved in violent episodes. On the other hand, high moral disengagers are less troubled by anticipatory feelings of guilt due to injurious conduct, that is, the higher the moral disengagement, the weaker the felt guilt and the lower the need to undo any harm caused by aggressive conduct (Bandura et al., 1996). High moral disengagers not only experience low guilt over injurious conduct but they are also less prosocial and less able to resist peer pressure for transgressive activities (Bandura et al., 1996, 2001; Kwak & Bandura, 1997).

Moreover, boys are more likely than girls to become moral disengagers over the course of development, although gender differences do not exist in the earlier years (Bandura, 2004; Bandura et al., 1996). Some findings from cross-cultural studies indicate that some of the gender differences in aggression may reside in the differential proclivity of disengaging moral self-sanctions from injurious conduct (Bandura, 1999, 2004).

Aim of Present Study: A Developmental Perspective

Our general aim was to examine the predictive power of different moral disengagement developmental trends in adolescence that are conducive to different levels of later aggressive and violent behaviors. To this aim, we used longitudinal structural equation modeling (i.e., growth latent curve and latent class growth analysis), a procedure not typically used in research on moral development. In particular, we first investigated the development of moral disengagement at a population level using growth latent curve analysis (Duncan & Duncan, 1994, 1995; Duncan, Duncan, & Hops, 1994; McArdle, 1988; McArdle & Anderson, 1989; McArdle & Hamagami, 1991; Meredith & Tisak, 1990; Muthén & Khoo, 1998; Stoolmiller, 1994) among an Italian adolescent sample from 14 to 20 years old. We hypothesized a decline in moral disengagement due to social, emotional, and cognitive skills that, over the course of development, enhance youths' capacities to regulate their own affect, to commit themselves to moral principles that ban aggression and violence, to accord their behavior to social standards that decrease behaviors that offend others, and to interact effectively with others (Eisenberg, Fabes, & Spinrad, 2006; Hart & Carlo, 2005; Tangney et al., 2007).

A second goal was to identify subgroups of adolescents following distinct developmental patterns of moral disengagement using latent class growth analysis, a semiparametric group-based approach (Nagin, 1999, 2005) that should be seen as a natural extension of growth models (Hoeksma & Kelderman, 2006). We hypothesized four trajectories, in accordance with what has been previously found in the aggression and in the aggressogenic personality factors literature (Barker, Tremblay, Nagin, Vitaro, & Lacourse, 2006; Brame et al., 2001; Broidy et al., 2003; Caprara, Paciello, Gerbino, & Cugini, 2007; Côté, Tremblay, Nagin, Zoccolillo, & Vitaro, 2002; Nagin & Tremblay, 1999; Tremblay & Nagin, 2005). We hypothesized a "nondisengaged" group whose moral disengagement would start and remain low, a "chronic" group whose moral disengagement would start and remain high, and two trajectories that could either decrease ("desister") or increase ("escalator") over the course of adolescence. To validate the trajectory model, the groups were compared on aggressive and violent behavior and a proxy of guilt across time (i.e., need of reparation; see Bandura et al., 1996; Caprara, Barbaranelli, Pastorelli, Cermak, & Rosza, 2001; Caprara, Manzi, & Perugini, 1992). We hypothesized that the chronic group would show higher levels of aggressive and violent behavior and lower levels of guilt and that the nondisengaged group would show lower levels of aggressive and violent behavior and higher levels of guilt over time.

Our third goal was to explore how gender is associated with moral disengagement development. We hypothesized that boys are more likely to exhibit higher levels of moral disengagement than girls in the course of development (Bandura et al., 1996) and that the decline in moral disengagement would be stronger in girls than in boys due to the higher resistance of girls to resort to direct aggression (Archer, 2004). As a consequence, we hypothesized that girls would have a higher probability of being members of a "nondisengaged" group, whereas boys would demonstrate a higher probability of being members of a "chronic" or "escalator" group.

Our fourth goal was to explore how peer evaluation of aggression in early adolescence is associated with moral disengagement development. Because it is more probable that adolescents who have already shown more aggressive behaviors in early adolescence could have more opportunities to recourse to moral disengagement, we hypothesized that the more preadolescents are evaluated as aggressive by peers, the higher the level of moral disengagement, the less the likelihood of declining during adolescence, and thus, the higher the probability of being a member of a "chronic" or "escalator" group and the lower the probability of being a member of a "nondisengaged" group.

Our final goal was to explore the association of moral disengagement development with aggressive and violent conduct in late adolescence, controlling for earlier peer evaluations of aggression. We hypothesized that the earlier preadolescents are inclined to use moral disengagement, and the more persistent recourse to it, the higher the engagement in aggression and violence. As a consequence, adolescents with a chronic high or increasing trajectory would show higher levels of aggression and violence relative to nondisengaged adolescents.

Method

Sample and Data Collection

The participants were part of an ongoing longitudinal project that began in 1989. We implemented this project to investigate the main determinants and pathways of aggression and successful development and adjustment from late infancy to early adulthood. The longitudinal project followed a staggered, multiple cohort design, with two cohorts assessed at five different time points. The first cohort was age 12 in 1994, the second cohort was age 12 in 1996 (Time 1). These participants were retested at age 14 (Time 2), at age 16 (Time 3), at age 18 (Time 4), and finally, at age 20 (Time 5). Cohort effects were previously tested and were found to be insignificant for sociodemographic and major study variables.

Three hundred and sixty-six adolescents (177 boys and 189 girls) were included in the study. Participants attended sixth grade at Time 1 and eighth grade at Time 2. Most of them attended high school at Times 3 and 4, whereas at Time 5, the majority were college students (71%). At Time 1, the participating adolescents were drawn from two schools in a residential community located near Rome, Italy. The community was composed of families of skilled workers, farmers, professionals, local merchants, and their service staff. Occupational socioeconomic distribution matched the national profile (Istituto Italiano di Statistica, 2002). The composition of the families also matched national data with regards to type of families and number of children. Most subjects were from intact (94.1%) and, on average, one-child families. The participation rate was high during longitudinal data collection, with 84.4% of the original sample (Time 1) returning at the final assessment time (Time 5). In particular, there were three patterns of missing data. Complete data were available for 65% of males and 83% of females. Thirty percent of males and 16% of females had missing data in one of the five waves. Finally, 5% of males and 1% of females had missing data in two of the five waves.

Procedures

Young adolescents at Times 1 and 2 were administered a set of scales tapping different types of dimensions in their classrooms by two trained female experimenters and were asked to complete the scales individually. Before starting, the experimenters explained that their responses to the questionnaires would be absolutely confidential. When necessary, the experimenters offered the children clarifications on the dimensions being measured. At Times 3, 4, and 5, participants were contacted by phone and invited to participate in the study for which they received a small payment. A stringent consent procedure for the research was followed including at various stages, parents' consent and approval from school councils, while letting children decline their participation if they so chose.

Measures

Moral disengagement (Bandura et al., 1996; Caprara et al., 1996). From Time 2 to Time 5, moral disengagement was assessed by self-report. The scale assesses proneness to moral disengagement of different forms of detrimental conduct in diverse contexts and interpersonal relationships. The full set of 32 items, presented in the Appendix, tap the eight different mechanisms by which moral self-sanctions can be disengaged from transgressive conduct as hypothesized by Bandura (1990, 1999). For each of the 32 items, adolescents rated on a 5-point Likert-type scale, their degree of acceptance of moral exonerations for such conduct on an agreement continuum (from 1 = *agree not at all* to 5 = *completely agree).*

Physical and verbal aggression scale (Caprara & Pastorelli, 1993). At Time 1, physical and verbal aggression was assessed by peer nominations. Children made their nominations from the roster of classmates in their classroom. Because this is a highly stable community, children were thoroughly acquainted with each other. Children were provided with a booklet containing all classmates' names. The respondents selected the three classmates who most frequently exert each of three different forms of physical and verbal aggression (kick and hit or punch, insult other kids or call them names, and hurt other kids). The numbers of nominations that each child received were summed separately and divided by the number of classmates (as a consequence this variable ranged from 0 = *never nominated by the classmates* to 1 = *nominated by all classmates*). Cronbach's reliability coefficient was .94.

From Time 2 to Time 5 physical and verbal aggression was assessed by self-report. This scale measured behaviors aimed to physically and verbally hurting others. It includes three items for physical aggression (i.e., "I hurt others") and three items for verbal aggression (i.e., "I say bad things about others kids") using a 3-point scale (from 1 = *never* to 3 = *often*) at Time 2 and a 5-point scale (from 1 = *never* to 5 = *often*) from Time 3 to Time 5. Cronbach's reliability coefficients ranged from .74 to .82 for physical aggression and from .68 to .72 for verbal aggression.

Violence (Caprara, Mazzotti, & Prezza, 1990). From Time 3 to Time 5, violence was assessed by self-report. This scale included 11 items aimed to assess the extent to which adolescents engage in violent conduct. For each item, adolescents rated how often they have engaged in violent actions, such as fighting, vandalism, or weapon use on a 5-point scale (from 1 = *never* to 5 = *often*). "Have you participated in violent actions of 'gangs'?" and "Have you ever had the occasion to use violence when there are arguments?" are two sample items. Cronbach's reliability coefficients ranged from .87 to .90.

Need for reparation (Caprara et al., 1992). From Time 2 to Time 5, need for reparation was assessed by self-report. This scale included five items measuring proneness to experience feelings of remorse, embarrassment, disturbance, tension, and desire for justice that are linked to the need for reparation of guilt-eliciting acts (i.e., "I feel that I have to make up for the wrongs that I've done to others") using a 6-point scale (from 1 = *completely true for me* to 6 = *completely false for me*). The Cronbach coefficients for this scale ranged from .65 to .71.

Results

Preliminary Analysis: Longitudinal Factorial Analysis

As a preliminary analysis, we first examined the dimensionality of the moral disengagement scale by using the exploratory factor analysis (EFA) approach. Second, we examined the longitudinal factorial invariance of moral disengagement to test the degree to which the construct is measured similarly across waves (Hoyle & Smith, 1994; Motl, Dishman, Birnbaum, & Lytle, 2005).

In accordance with previous studies on moral disengagement (Bandura et al., 1996; Caprara et al., 1996), two alternative models for each wave were hypothesized: (a) an eight-factor solution, each factor representing a distinct mechanism of moral disengagement, and (b) a one-factor solution, consistent with previous studies.

To identify the best solution, we analyzed the eigenvalues (Cattell & Vogelmann, 1977) and considered the standardized root mean square residual (SRMR; Jöreskog & Sörbom, 1984) and the root mean square error of approximation (RMSEA; Steiger & Lind, 1980) as indices of goodness of fit. Because several items presented a deviation from a normal distribution, EFA was performed using maximum likelihood parameter estimates with standard errors and the chi-square test statistic, which are robust to nonnormality (MLMV). Factors were rotated using the Promax procedure.

For Time 2, the first 10 eigenvalues of the correlation matrix were: 7.19, 2.21, 1.54, 1.36, 1.26, 1.12, 1.02, 0.98, and 0.94. The eight-factor solution did not converge. The analysis of eigenvalues suggested a one-factor solution. This model fit the data ($\chi^2 = 1192.19$, $df = 464$, $p < .001$, RMSEA = .06, SRMR = .07), reproducing with a good approximation the intercorrelation among the 32 items of the scale. Cronbach's reliability coefficient for this wave was .87.

For Time 3, the first 10 eigenvalues of the correlation matrix were: 10.67, 2.17, 1.68, 1.40, 1.26, 1.07, 0.99, 0.91, 0.88, and 0.82. The eight-factor solution did not converge. The analysis of eigenvalues suggested a one-factor solution. This model fit the data ($\chi^2 = 1291.78$, $df = 464$, $p < .001$, RMSEA = .07, SRMR = .07), reproducing with a good approximation the intercorrelation among the 32 items of the scale. Cronbach's reliability coefficient for this wave was .93.

For Time 4, the first 10 eigenvalues of the correlation matrix were: 9.99, 2.20, 1.61, 1.42, 1.31, 1.24, 1.04, 0.99, 0.96, and 0.90. Although the RMSEA and the SRMR of the eight-factor model resulted in a good approximation to the data (RMSEA = .03, SRMR = .03), the pattern of rotated factor loadings was not interpretable or simple (Thurstone, 1947). The analysis of eigenvalues suggested a one-factor solution. This model fit the data ($\chi^2 = 1322.68$, $df = 464$, $p < .001$, RMSEA = .07, SRMR = .07), reproducing with a good approximation the intercorrelation among the 32 items of the scale. Cronbach's reliability coefficient for this wave was .92.

For Time 5, the first 10 eigenvalues of the correlation matrix were: 9.15, 2.19, 1.95, 1.51, 1.39, 1.19, 1.08, 1.01, 0.90, and 0.87. Although the RMSEA and the SRMR of the eight-factor model resulted in a good approximation to the data (RMSEA = .03, SRMR = .03), the pattern of rotated factor loadings was not interpretable or simple (Thurstone, 1947). The analysis of eigenvalues suggested a one-factor solution. This model fit the data ($\chi^2 = 1293.32$, $df = 464$, $p < .001$, RMSEA = .08, SRMR = .09). Cronbach's reliability coefficient for this wave was .91.

The above findings substantially corroborated previous results (Bandura et al., 1996; Caprara et al., 1996) and attest to a main latent dimension, which includes all the items measuring the eight moral disengagement mechanisms. As a next step, we analyzed the longitudinal factor structure of moral disengagement across the four waves of data (14–20 years) testing a series of nested models, from less to more demanding ones. As Meredith (1993) and Widaman and Reise (1997) have argued, there are different levels of invariance. *Configural invariance* (Thurstone, 1947) hypothesizes the equality of the overall structure (i.e., same factor and same patterns of fixed and freed parameters) across groups or time. *Metric* or *pattern invariance* (Thurstone, 1947) hypothesizes the equality of the factor loadings across time or groups. *Strong factorial invariance* (Meredith, 1993) hypothesizes the equality of the intercept of the measured variables across time or groups. *Strict factorial invariance* (Meredith, 1993) hypothesizes the equality of the uniqueness of the measured variables across time or groups.

Given the small size of the longitudinal sample and the number of indicators of moral disengagement, the longitudinal invariance was analyzed via item parceling (Anderson & Gerbing, 1988; Hoyle 1995; Martinez, Black, & Starr, 2002). Parceling typically exhibits a distribution that more closely approaches a normal distribution than using the original items as individual indicators (West, Finch, & Curran, 1995). Thus, with the aim of reducing the variance–covariance matrix to be analyzed, we built four parcels for each wave. We used item-scale correlation to select items. In particular, items were assigned to parcels so that equivalent parcels in terms of homogeneity were created, and the monodimensionality of each parcel was guaranteed as suggested by Bandalos and Finney (2001).

In all models, autocorrelations were estimated among all pairs of uniqueness because the same parcels were used across the four time points (Motl et al., 2005; Pitts, West, & Tein, 1996). To compare the fit of the nested models in the longitudinal invariance sequence, we used the chi-square difference test (Bollen, 1989; Fix, Hodges, & Lehmann, 1959) and the difference in comparative fit index (CFI; Bentler, 1989); as noted by Cheung and Rensvold (2002), a difference larger than .01 in CFI would indicate a meaningful change in model fit.

The fit indices for the models tested in the invariance analyses are presented in Table 1. As can be noted, configural and metric invariance were supported by all fit indices. Although full strong invariance was not supported, support for partial strong invariance came from differences in the CFI. Finally, support for a strict factorial invariance only came from differences in the CFI. Because the majority of loadings were invariant, results confirmed that the constructs were measured as comparable over time (Raykov, 2004; Raykov & Marcoulides, 2006).

Descriptive Statistics

Observed means of moral disengagement from Time 2 to Time 5, peer evaluation of physical and verbal aggression measured at Time 1, and the outcomes (violence and physical and verbal aggression) measured at Time 5, separately for males and females, are reported in Table 2.

As shown, there were missing data in all the variables. As noted by Hanson, Tobler, and Graham (1990), in longitudinal research, it is common to have subject attrition, which produces missing values in the data set. In the presence of missing data, estimation of parameters must be adjusted accordingly. Among the different methods used for taking into account missing data, we used the maximum likelihood estimation of parameters, a method widely accepted as appropriate for handling missing data (Muthén & Shedden, 1999; Schafer & Graham, 2002) under the assumption that the data are missing at random (Arbuckle, 1996; Little, 1995).

Before proceeding with the analysis, the normality of the variables was ascertained. Due to the non-normality of some measures (the skewness and kurtosis varied from 2.23 for physical aggression to 10.79 for violence), we computed the inverse of violence and physical aggression and the root square of peer evaluation of physical and verbal aggression to normalize these variables as suggested by Tabachnik and Fidell (1989). The skewness and kurtosis of the computed outcomes varied from −.572 for physical aggression to −1.29 for violence.

Correlations between moral disengagement across the four time points, peer evaluation of physical and verbal aggression, and the three outcomes—physical and verbal aggression and violence—for boys and girls are provided in Table 3. As shown, they attested to a high-medium stability of moral disengagement

Table 1
Fit Indices for the Model of the Invariance Routine

Model	χ^2	*df*	*p*	CFI	RMSEA	SRMR					
Baseline											
14 years	.806	2	.67	1.00	.00 (.00 – .08), $p = .84$	.005

VERB	137	1.97	0.75	172	1.61	0.58
VIO	136	1.40	0.52	170	1.11	0.21

Note. MD14 = moral disengagement at age 14; MD16 = moral disengagement at age 16; MD18 = moral disengagement at age 18; MD20 = moral disengagement at age 20; AGG_PE = physical and verbal aggression peer evaluation at age 12; PHY = physical aggression at age 20; VERB = verbal aggression at age 20; VIO = violence at age 20.

over time with lower correlations the longer the distance of time. Finally, peer evaluation of physical and verbal aggression and the outcomes were correlated with the moral disengagement variable, especially in boys.

Growth Models

The analysis of moral disengagement development was carried out within a latent variable framework. We specified a multigroup growth curve model that simultaneously estimated the same pattern of relationships among variables for males and females. To examine gender differences in the estimated parameters, we constrained all parameters to be equal across groups and used the chi-square difference test to compare nested models. Modification indices were used to assess the tenability of the equality constraint imposed across gender.

Table 3

Correlations Between Moral Disengagement From Ages 14 to 20, Physical and Verbal Aggression at Age 12, and Aggressive and Violent Conduct at Age 20, Separately for Gender

	1	2	3	4	5	6	7	8
1. AGG_PE		*.09*	*.11*	.27	.21	*.12*	.16	.17
2. MD14	.21		.51	.40	.43	*.11*	*.01*	*.05*
3. MD16	.29	.49		.66	.52	.17	.15	.21
4. MD18	.21	.44	.58		.64	.22	.21	.22
5. MD20	.18	.39	.37	.65		.41	.32	.42
6. VERB	*.15*	.39	.25	.37	.50		.33	.41
7. PHY	.16	.31	.32	.42	.53	.67		.57
8. VIO	.25	.21	.32	.37	.40	.45	.53	

Note. Values below the diagonal are for males. Values above the diagonal are for females. All correlation coefficients were significant at least at $p < .05$, except for those that are in italics, which are not significant. Agg_PE = physical and verbal aggression peer evaluation at age 12; MD14 = moral disengagement at age 14; MD16 = moral disengagement at age 16; MD18 = moral disengagement at age 18; MD20 = moral disengagement at age 20; PHY = physical aggression at age 20; VERB = verbal aggression at age 20; VIO = violence at age 20.

We defined two latent growth factors from multiple indicators, that is, the four repeated measures of moral disengagement. The first factor was labeled intercept and represents the initial starting point of moral disengagement. The second factor represents the slope or the shape of the trajectory over time. The following equation shows the mathematical representation of the growth model:

$$y_t = \eta_0 + \eta_1 x_t + \varepsilon_t; \quad \text{where } t = \text{Times } 2, 3, 4, 5,$$

where y_t = observed score at time t, η_0 = unobserved score for the intercept factor, η_1 = unobserved score for the growth rate factor, and x_t = factor loading relating y_t to latent growth variables.

Because the factor loadings of the slope give the shape of the growth, a series of models were tested and compared with each other. In this way, we could determine the parameterization that best fit the data. In all the models tested, we defined the intercept as moral disengagement at age 14 by fixing the factor loading relating this variable to the slope at 0.

Following McArdle and Anderson (1989), the first model tested was a no-growth model (only intercept), $\chi^2(14, N = 177, 188) = 419.497$, $p < .001$, CFI = .08, RMSEA = .398 (.366, .482), SRMR = .779. This model assumed that the level of moral disengagement was stable over time except for a random error component at each time of evaluation. The second was a linear model representing a constant change over time, $\chi^2(8, N = 177, 188) = 70.668$, $p < .001$, CFI = .86, RMSEA = .207 (.164, .253), SRMR = .077. In this model, we fixed the factor loadings on the slope at 0, 1, 2, and 3. The third model examined a nonlinear growth where the form of the change over time was not specified a priori, $\chi^2(6, N = 177, 188) = 4.086$, $p = .67$, CFI = 1.00, RMSEA = .000 (.000, .077), SRMR = .040. Finally, the fourth model was the nonlinear model without the intercept, $\chi^2(12, N = 177, 188) = 88.738$, $p < .001$, CFI = .83, RMSEA = .187 (.152, .225), SRMR = .230. In particular, we fixed the first factor loadings on the slope and estimated the others. In all the growth models, autocorrelations between the same measures over time were estimated and for model identification, two uniquenesses and two covariances between uniquenesses were constrained to be equal among males and females. Because these models are nested, we performed a chi-square differences test to compare the models (Bollen, 1989; Fix et al., 1959). This test revealed that the nonlinear model provided the best fit to the data compared to the no-growth model, $\Delta\chi^2(8) = 415.41$, $p < .001$; the linear growth model, $\Delta\chi^2(2) = 66.58$, $p < .001$; and the nonlinear without intercept model, $\Delta\chi^2(6) = 84.65$, $p < .001$. Then, we tested if there were any differences among males and females on the free factor loadings, constraining these parameters to be equal among the two groups and used the chi-square difference test to compare the constrained model with the nonconstrained one. Results showed that the free factor loadings on the slope ($x_4 = 1.282$, $x_5 = 1.513$) were the same for males and females, $\Delta\chi^2(2) = 1.57$, $p = .46$, and were significantly smaller than the linear loadings ($x_4 < 2$ with $p < .001$, $x_5 < 3$ with $p < .001$), indicating that the decrease in moral disengagement from ages 14 to 16 was larger than both the decrease from ages 16 to 18 and the decrease from ages 18 to 20.

Table 4
Growth Curve Parameters

	Males		Females	
Growth parameters	Effect	*t* value	Effect	*t* value
Mean				
Intercept[a]	2.68	78.25	2.51	75.51
Slope[a]	−0.36	−11.67	−0.46	−13.61
Variances				
Intercept	0.19	3.66	0.19	3.66
Slope	0.08	2.61	0.08	2.61
Correlation				
Intercept ↔ slope	−.061	−2.06	−0.61	−2.06

Note. The *t* values greater than 1.96 (1.65 for variances) in magnitude indicate a parameter estimate that is significantly different from zero (for $p < .05$). Parameters estimated for correlation (↔) are presented in standardized form. All other parameter estimates are presented in unstandardized form.
[a] Parameter is different for males and females.

The results of the final model, $\chi^2(9, N = 177) = 5.096$, 188, $p = .83$, CFI = 1.00, RMSEA = .000, CI = .000, .050, SRMR = .065, summarized in Table 4 and Figure 1, suggest that there were gender differences in the initial level of moral disengagement; that is, males exhibited higher levels of moral disengagement than females at age 14—we compared the model with the mean of the intercept constrained to be equal among males and females with the nonconstrained model, $\Delta\chi^2(1) = 13.03$, $p < .001$. Furthermore, the mean of the slope indicated a significant decrease from ages 14 to 16. In particular, females exhibited a greater decline than males—we compared the model with the mean of the slope constrained to be equal among males and females with the nonconstrained model, $\Delta\chi^2(1) = 7.64$, $p < .001$. The variances of the growth factors were also estimated and they suggested that there was a significant variation in individual differences in the initial status and in the growth rate and that these were the same for both males and females—we compared the model with the variance of the intercept and the variance of slope constrained to be equal among males and females with the nonconstrained model, $\Delta\chi^2(2) = .08$, $p = .96$. Finally, results demonstrate that the covariance between the initial level and the slope was significantly negative and equal for males and females, that is, the higher the level of moral disengagement at age 14, the less the change of moral disengagement during adolescence—we compared the model with the covariance among intercept and slope constrained to be equal among males and females with the nonconstrained model, $\Delta\chi^2(1) = .59$, $p = .44$.

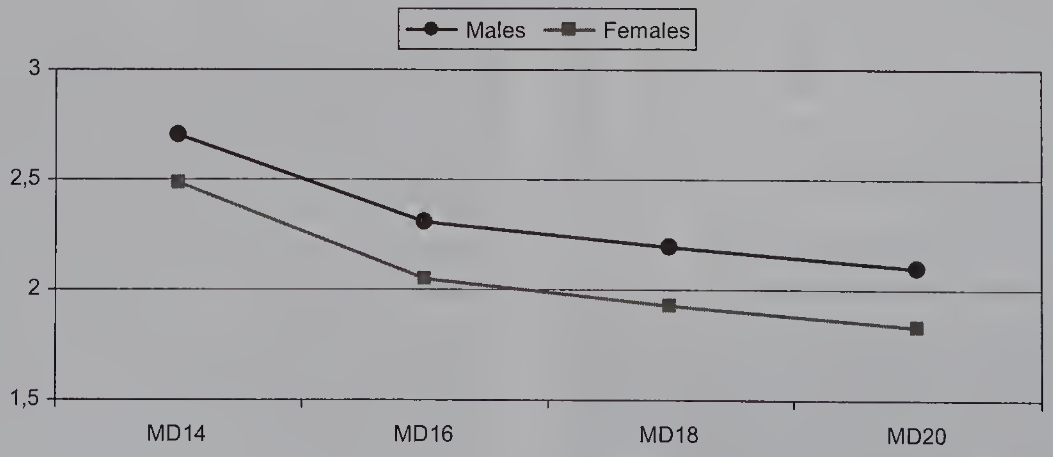

Figure 1. Moral disengagement development.
Note. MD14 = moral disengagement at age 14; MD16 = moral disengagement at age 16; MD18 = moral disengagement at age 18; MD20 = moral disengagement at age 20.

After ascertaining the best fitting growth curve, we added the covariate peer evaluation of physical and verbal aggression at age 12 and the three outcomes to examine the influence exerted by the covariate on moral disengagement at age 14, on its development during adolescence, and on physical and verbal aggression and violence at age 20 separately for males and females. Furthermore, we examined the influence exerted by moral disengagement at age 14 and its development during adolescence on physical and verbal aggression and violence at age 20. The fit indices of the model suggested a good approximation of the model to the data. In particular, $\chi^2(34, N = 177, 188) = 28.077$, $p = .75$, CFI = 1, RMSEA = .000 (.000 – .039), SRMR = .082.

The results of the regression part of this model, summarized in Table 5, indicate that peer evaluation of physical and verbal aggression at age 12 significantly predicted a higher level of moral disengagement at age 14 for both males and females. Peer evaluation of physical and verbal aggression at age 12 affected physical and verbal aggression at Time 5 only indirectly through moral disengagement at age 14 (intercept; for physical aggression: male, $\beta = .17$, $z = 3.415$; female, $\beta = .11$, $z = 2.647$; for verbal aggression: male, $\beta = .18$, $z = 3.472$; female, $\beta = .12$, $z = 2.783$). Moreover, peer evaluation of physical and verbal aggression at age 12 directly affected violence at Time 5 for males only and indirectly through moral disengagement at age 14 (intercept) both for males and females (male: $\beta = .11$, $z = 3.421$; female: $\beta = .14$, $z = 2.954$). Furthermore, moral disengagement measured at age 14 significantly predicted physical and verbal aggression and violent behavior 6 years later for both males and females. In particular, the higher the level of moral disengagement at age 14, the higher the levels of physical and verbal aggression and violence problems at age 20. In addition, results suggested that the more moral disengagement decreased from age 14 to 16, the lower the expected levels of physical and verbal aggression and violence at age 20 for both males and females. The model accounted for 33% and 24% of the variance of verbal aggression, 34% and 25% of the variance of physical aggression, and 28% and 34% of the variance of violence for males and females, respectively.

Table 5
The Effect of the Growth Curve of Moral Disengagement on Aggressive Behavior

	Males		Females

Note. The values greater than 1.96 (1.65 for variances) in magnitude indicate a parameter estimate that is significantly different from zero (for $p < .05$). Parameters estimated for correlation (↔) and regression (predictor → outcome) are presented in standardized form. PHY = physical aggression at age 20; VERB = verbal aggression at age 20; VIO = violence at age 20; Agg_Pe = physical and verbal aggression peer evaluation at age 12.
[a]Parameter is different for males and females.

Trajectory Model

A semiparametric group-based approach (Nagin, 1999, 2005) was then used to identify developmental trajectories. The Bayesian information criterion (BIC; Schwarz, 1978) was used to determine the optimal number of groups. This method allows: (a) the identification of subgroups of individuals following distinct developmental trajectories for a given dimension, (b) the estimation of the proportion of individuals following each trajectory, and (c) the estimation of the stability of each subgroup over time (i.e., the shape of each trajectory over time). Censored normal models were estimated. A detailed description of the statistical rationale underlying the trajectory estimation procedure is given elsewhere (e.g., Jones & Nagin, 2007; Jones, Nagin, & Roeder, 2001; Nagin, 1999, 2005).

The analysis proceeded in four stages. First, the optimal number of groups was identified and models with various specifications for stable, linear, quadratic, or cubic shapes of the moral disengagement trajectory groups were estimated. In the second stage, after ascertaining the best trajectory model, we tested whether and how much gender and peer evaluation of physical and verbal aggression at age 12 affected the probability of group membership. In the third stage, we validated the trajectory model examining the profiles of each group on four correlates across time. In particular, we considered physical aggression, verbal aggression, violence, and need for reparation. Finally, the linkage between trajectories of moral disengagement and aggressive and violent outcomes at age 20 was tested (Nagin, 1999).

First stage: Identification of the developmental model. A four-group unconditional model showed the best fit to the data (BIC = −867.58). The four-group model was respecified considering gender and peer evaluation of physical and verbal aggression as predictors of the trajectory group membership probability. The four-group conditional model was confirmed as the best model (BIC = −832.89). Figure 2 presents the size and the shapes of the trajectory groups.

The developmental trajectory model suggested the following groups:

- Nondisengaged group: composed of 37.9% of the adolescents characterized by a quadratic trend with initially low levels of moral disengagement followed by a significant decline;
- Normative group: composed of 44.5% of the adolescents characterized by a cubic trend with initially moderate levels of moral disengagement followed by a significant decline;
- Later desister group: composed of 6.9% of the adolescents characterized by a cubic trend with initially high-medium levels of moral disengagement followed by a significant increase from ages 14 to 16 and an even more significant decline from ages 16 to 20;
- Chronic group: composed of 10.7% of the adolescents with constant medium-high levels of moral disengagement.

Table 6 presents the correlations between the actual grouping variables (dichotomous) and the posterior group membership probabilities.

With regard to the gender distribution of the group trajectories, there were a higher proportion of boys in the chronic group and a higher proportion of girls in the nondisengaged group (see Figure 2).

Second stage: Linking group membership to gender and aggressive predictor. Table 7 presents the results of the multinomial logit regression used to examine whether and how much gender and peer evaluation of physical and verbal aggression affected the probability of group; membership. The first panel of Table 4 shows coefficient estimates and *t* statistics. The normative group served as the contrast group. Relative to the normative group, gender significantly increased the probability of membership in the nondisengaged group; that is, females had a higher probability of being in this group than did males. Furthermore, higher levels of peer evaluation on physical and verbal aggression significantly increased the probability of membership in the chronic and later desister groups (α = .05, one-tailed test).

The second panel of Table 7 shows the predicted probabilities of group membership based on the coefficient estimates. Both males and females who were never nominated by their classmates had a high probability of belonging to the normative or

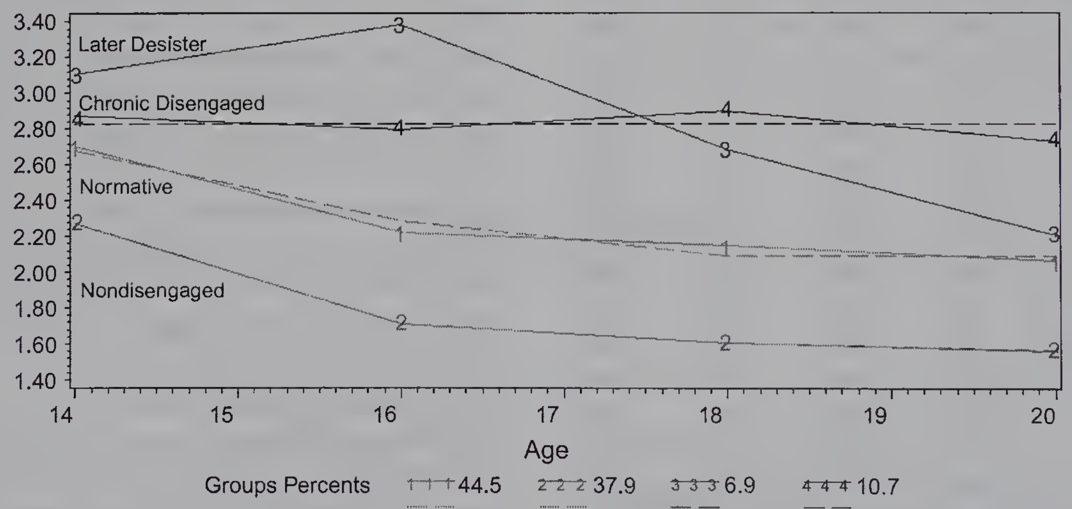

Figure 2. Moral disengagement trajectories.

Note. The continuous lines represent trajectories of actual moral disengagement calculated as mean scores for adolescents in groups identified by Proc traj procedure. The broken lines represent predicted moral disengagement calculated with model's coefficient estimates. Gender distribution in each trajectory group: nondisengaged group: 23.1% male and 76.9% female (of the total sample, 18.7% male and 54.8% female); normative group: 54.7% male and 45.3% female (of the total sample, 52.4 % male and 38.3% female); chronic disengaged group: 89.7% male and 10.3% female (of the total sample, 21.1% male and 2.1% female); later desister group: 59.1% male and 40.9% female (of the total sample, 7.8% male and 4.8% female).

Table 6

Correlation Between the Actual Grouping Variables and the Posterior Group Membership Probabilities

	Normative PRB	Nondisengaged PRB	Later desister PRB	Chronic PRB
Normative	.94	−.62	−.24	−.28
Nondisengaged	−.65	.95	−.26	−.32
Later desister	−.25	−.23	.95	*−.01*
Chronic disengaged	−.30	−.32	*.05*	.95

Note. All correlation coefficients were significant at least at $p < .05$, except for those in italics, which are not significant. PRB = posterior probabilities.

nondisengaged groups (.86 and .96, respectively), but while females had a higher probability of being a member of the nondisengaged group (.61), males had a higher probability of being a member of the normative group (.55).

Considering a high-risk scenario in which adolescents were nominated by all classmates, the predicted probability for males of being a member of the chronic group was .38, whereas it was .10 in the previous scenario. In a similar way, the predicted probability for females of being a member of the chronic group was .14, whereas it was .02 in the previous scenario. Furthermore, both males and females had a high-predicted probability to belong to the later desister or normative group (.58 and .70, respectively). Finally, the predicted probability of males being a member of the nondisengaged group was .04 instead of .31 in the previous scenario. In a similar way, the predicted probability for females to be a member of the nondisengaged group was .15, whereas it was .61 in the previous scenario.

Third stage: Trajectories profiles on aggression, violence and need for reparation. Figure 3 shows the profiles in physical aggression, verbal aggression, violent conduct, and need for reparation for each group across time.

As shown, the four trajectory groups significantly differed on physical aggression (Duncan post hoc test). At ages 14, $F(3, 229) = 40.02$, $p < .000$, $\eta^2 = .21$, and 16, $F(3, 317) = 42.47$, $p < .001$, $\eta^2 = .29$, all four groups were different from each other. In particular, the later desister group showed the highest level of physical aggression, whereas the nondisengaged group showed the lowest level. At age 18, $F(3, 330) = 44.94$, $p < .001$, $\eta^2 = .29$, the nondisengaged group showed the lowest level of physical aggression, whereas the later desister and chronic groups did not differ from each other and showed the highest level. Finally, at age 20, $F(3, 299) = 22.02$, $p < .001$, $\eta^2 = .18$, the chronic group showed the highest level of physical aggression.

With regard to verbal aggression, the four trajectory groups were significantly different (Duncan post hoc test). In particular, at age 14, $F(3, 330) = 20.01$, $p < .000$, $\eta^2 = .15$, the later desister and chronic groups did not differ from each other and showed the highest level of verbal aggression. At age 16, $F(3, 317) = 37.38$, $p < .001$, $\eta^2 = .26$, the later desister and chronic groups did not differ from each other and showed the highest level of verbal aggression and the nondisengaged showed the lowest. At age 18, $F(3, 330) = 42.53$,

Table 7

The Impact of Gender and Physical and Verbal Aggression Peer Evaluated on Group Membership Probabilities

	Groups			
	Later desister disengaged	Chronic disengaged	Normative	Nondisengaged
	Multinomial logit coefficients (with ± statistics given in parenthesis)			
Constant	−2.67 (−3.87)	−2.84 (−3.45)	—	0.56 (1.86)
Gender	−0.05 (0.09)	−1.15 (−1.37)	—	−1.12 (−3.38)
Agg_Pe	2.78 (2.11)	2.01 (1.89)	—	−1.38 (−1.46)
	Predicted membership probabilities based on multinomial model coefficient estimates			
Males and Agg_Pe = 0	.04	.10	.55	.31
Females and Agg_Pe = 0	.02	.02	.35	.61
Males and Agg_Pe = 1	.30	.38	.28	.04
Females and Agg_Pe = 1	.37	.14	.33	.15

Note. Agg_Pe = physical and verbal aggression peer evaluation at age 12. Agg_Pe = 0: *never nominated by classmates*; Agg_Pe = 1: *nominated by all classmates.*

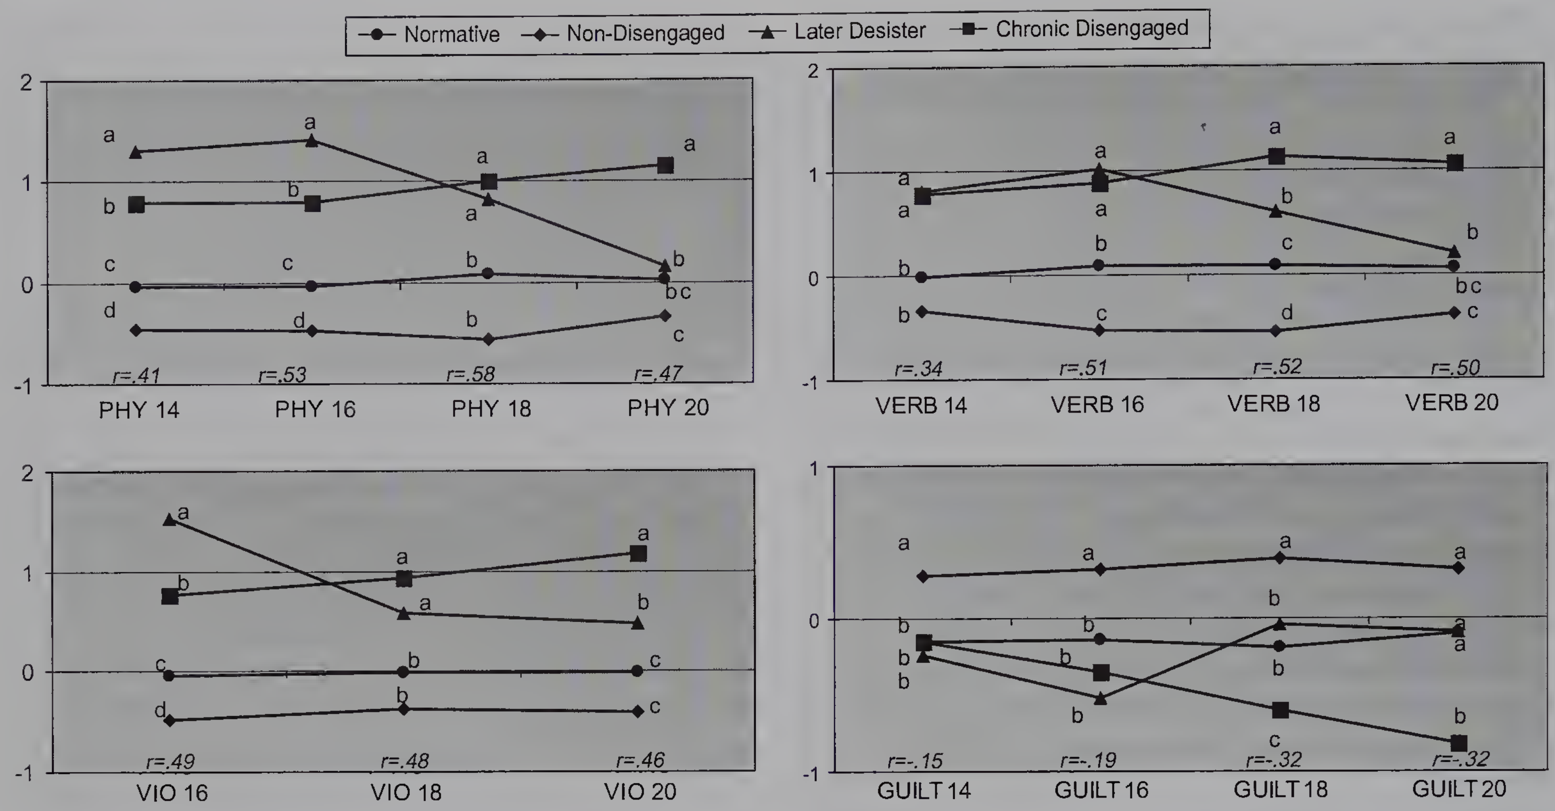

Figure 3. Trajectories profiles on aggressive behavior, violence, and need for reparation.
Note. PHY14 = physical aggression at age 14; PHY16 = physical aggression at age 16; PHY18 = physical aggression at age 18; PHY20 = physical aggression at age 20; VERB14 = verbal aggression at age 14; VERB16 = verbal aggression at age 16; VERB18 = verbal aggression at age 18; VERB20 = verbal aggression at age 20; VIO16 = violence at age 16; VIO18 = violence at age 18; VIO20 = violence at age 20; GUILT14 = need for reparation at age 14; GUILT16 = need for reparation at age 16; GUILT18 = need for reparation at age 18; GUILT20 = need for reparation at age 20. In each figure correlations between moral disengagement and each variable are reported for each time point.

$p < .001$, $\eta^2 = .28$, all four groups were different from each other. In particular, the chronic group showed the highest level of verbal aggression and the nondisengaged the lowest. Finally, at age 20, $F(3, 299) = 21.53$, $p < .001$, $\eta^2 = .18$, the chronic group showed the highest level of verbal aggression, whereas the normative and later desister groups did not differ from each other.

With regards to violence, the four trajectory groups were significantly different (Duncan post hoc test). In particular, at age 16, $F(3, 317) = 48.02$, $p < .000$, $\eta^2 = .31$, all four groups were different from each other. In particular, the later desister group showed the highest level of violence. At age 18, $F(3, 330) = 24.42$, $p < .001$, $\eta^2 = .18$, the chronic and later desister groups did not differ from each other and showed the highest level of violence. Finally, at age 20, $F(3, 286) = 27.33$, $p < .001$, $\eta^2 = .22$, the chronic group showed the highest level of violence, whereas the later desister group showed higher levels of violence than the normative and nondisengaged groups.

Finally, the four trajectory groups significantly differed on need for reparation (Duncan post hoc test). In particular, at ages 14, $F(3, 246) = 5.44$, $p < .000$, $\eta^2 = .05$, and 16, $F(3, 327) = 8.92$, $p < .001$, $\eta^2 = .08$, the nondisengaged group showed the highest level of need for reparation. At age 18, $F(3, 342) = 15.02$, $p < .001$, $\eta^2 = .12$, the nondisengaged group showed the highest level and the chronic showed the lowest. Finally, at age 20, $F(3, 299) = 12.60$, $p < .001$, $\eta^2 = .11$, the chronic group showed the lowest level of need for reparation, whereas the other three groups did not differ.

In each figure, the correlations between moral disengagement and each variable were reported. As shown, moral disengagement was positive and highly correlated with physical and verbal aggression and violence and negatively correlated with need of reparation in each time point.

Fourth stage: The impact of moral disengagement trajectories on aggressive and violent conduct. Table 8 presents the correlations between the posterior probabilities of group membership for each individual and aggressive and violent conduct at age 20.

As shown, aggressive and violent outcomes were positively and significantly correlated with the posterior probability of being in the chronic or later desister groups. On the contrary, the outcomes were negatively and significantly correlated with the

Table 8

Correlations Between the Posterior Probabilities of Group Membership and Physical and Verbal Aggression and Violence at Age 20

Posterior probabilities	Verbal aggression	Physical aggression	Violence
Normative	*.07*	*.04*	*.10*
Nondisengaged	−.35	−.33	−.42
Later desister	.10	.17	.20
Chronic	.39	.36	.39

Note. All correlation coefficients were significant at least at $p < .05$, except the one that is underlined, which is significant at $p < .10$, and those that are italics, which are not significant.

posterior probability of being in the nondisengaged group. Moreover, correlations were not significant between outcomes and the posterior probability of being in the normative group.

To test the linkage between trajectories of moral disengagement and the three outcomes (i.e., physical aggression, verbal aggression, and violent behaviors at age 20), three hierarchical regression analyses were conducted. In these models, gender, peer evaluation on physical and verbal aggression at age 12, and the posterior probabilities of group membership were considered independent variables. In entering the posterior probabilities, we excluded the probability of group membership for one of the groups because the posterior probabilities of group membership in each group added to 1 for a given individual (e.g., the independent variables would be perfectly correlated). We decided to exclude the probability of being in the normative group.

As a preliminary step, we evaluated whether these analyses needed to be conducted separately for males and females. In this regard, the interaction of Gender × Peer Evaluation on Physical and Verbal Aggression and the interaction of Gender × The Different Group Membership Probabilities were included as independent variables in the hierarchical regression model. In particular, gender was entered at Step 1, peer evaluation of physical and verbal aggression was entered at Step 2, the interaction of Gender × Peer Evaluation of Physical and Verbal Aggression was entered at Step 3, the different group membership probabilities were entered at Step 4, and the interaction of Gender × The Different Group Membership Probabilities were entered at Step 5. The analysis revealed no statistically significant interactions; therefore, our subsequent hierarchical regression analyses were performed with gender as a factor rather than separately for the two gender groups.

The final hierarchical regression models are presented in Table 9. The results of the three hierarchical models showed that gender significantly predicted the three outcomes, especially violence (17% of explained variance). Moreover, peer nomination of physical and verbal aggression at age 12 significantly predicted higher levels of physical and verbal aggression and violent conduct at age 20 (the explained variance ranged from 2% to 5%).

In addition to the contribution of gender and earlier peer evaluations of aggressive behavior, the posterior probability of group membership significantly predicted the three outcomes (the explained variance ranged from 10% to 13%). In particular, the probability of being in the chronic group was positively and significantly linked with verbal aggression, physical aggression, and violence, whereas the probability of being a member of the nondisengaged group was negatively and significantly linked with aggression and violence.

Table 9

Results of Hierarchical Regression of Trajectories on Physical and Verbal Aggression and Violence at Age 20

		Verbal aggression				Physical aggression				Violence			
Step		β_1	β_2	β_3	R^2 change	β_1	β_2	β_3	R^2 change	β_1	β_2	β_3	R^2 change
1	Gender	.16***	.19**	*ns*	.07***	.23***	.15**	*ns*	.05***	.41***	.30***	.18***	.17***

Note. β_1 = beta coefficients before entering trajectories probabilities and levels of outcomes at Time 1; β_2 = coefficients before entering trajectories probabilities; β_3 = final beta coefficients; R^2 change = change in R^2—for the first step it refers to R^2; Agg_Pe = physical and verbal aggression peer evaluation at age 12.

†Significant at $p \leq .07$. **Significant at $p \leq .01$. ***Significant at $p \leq .001$.

Discussion

As previous studies have highlighted (Bandura, 1999; Bandura et al., 1996, 2001; Caprara et al., 1996), the longitudinal findings of the present study attested to the important predictive role that moral disengagement plays in the study of aggressive and violent behaviors. At the population level, for both boys and girls, the developmental model attested to the general tendency of moral disengagement to decline over time. In particular, moral disengagement decreased strongly between ages 14 and 16 and less evidently until age 20. The general decrease in moral disengagement could be specific to the developmental period from early adolescence (junior high school) to adolescence (high school), which is characterized by new challenges related to educational and social role transitions. It could reflect a change in cognitive and social structures and processes through development of the capacity to assign meaning, to anticipate outcomes, to plan actions, and to learn from social experiences the value of assigning different behaviors. Generally, over the course of maturation, individuals' social adjustment and self-regulatory abilities improve and their ability to infer the perspective of others increases (Bandura, 1991, 2004), promoting moral reasoning and moral agency (Eisenberg, 2000; Eisenberg et al., 2006). Indeed, adolescents are exposed to novel "role-taking opportunities" and moral dilemmas with personally relevant consequences to the self and to others (Hart & Atkins, 2002; Hart, Atkins, Markey, & Youniss, 2004). It may be that these refinements in skills are indispensable in preventing disengagement in "moral life" during adolescence, a time when individuals start to become more responsible and agentic in their social life than was typically possible in childhood (Hart & Carlo, 2005).

Furthermore, results attested to the significant variation in individual differences in the initial status and in the general developmental pathway of moral disengagement, supporting the importance of further exploring interindividual differences during development. At this level, the developmental trajectories model confirmed what was found at the population level and provides a more comprehensive picture of the development of moral disengagement. In fact, although distinct groups of adolescents followed different developmental trends, most adolescents (89%) decreased their level of moral disengagement during this time. As expected, the best developmental trajectory model included four different trajectory groups in accordance with the existing aggression literature (Barker et al, 2006; Brame et al., 2001; Broidy et al., 2003; Côté et al., 2002; Nagin & Tremblay, 1999; Tremblay & Nagin, 2005) and other developmental studies on aggressogenic personality factors such as irritability and hostile rumination, which have been shown to be related to moral disengagement and aggression (Caprara et al., 2007). The largest group may be considered as representing the "normative" group and started with medium levels of moral disengagement, which subsequently decreased during development. A similar trend was followed by the group called "nondisengaged," which started with lower levels of moral disengagement than the normative group. The last two smaller groups started with initial high-medium levels of moral disengagement but followed different developmental trends. The "later desister group" showed a discontinuous pattern of moral disengagement decrease. In particular, their level of moral disengagement increased from ages 14 to 16 and then strongly decreased from ages 16 to 20. In contrast, the "chronic group" showed stable levels of moral disengagement during adolescence. Although these two groups demonstrated similar physical and verbal aggression and violence profiles from ages 14 to 16; from ages 18 to 20, they showed different developmental trends: The chronic group maintained their high levels of aggression, whereas the later desister group demonstrated decreasing levels of aggression. These two groups were similar to findings of previous longitudinal studies that have identified a group of youth who show chronically high levels of antisocial and aggressive behavior during adolescence and adulthood (Brame et al., 2001; Moffitt, Caspi, Harrington, & Milne, 2002) and a group that later decrease their level of problematic behaviors during adolescence (Moffitt, 1993; Nagin, Farrington, & Moffit, 1995).

Both the later desister and chronic groups call one's attention to two possible developmental trends for adolescents that show high levels of moral disengagement at age 14. Later desister adolescents decrease their level of moral disengagement probably by improving, over the course of maturation, their cognitive and emotional skills, even if they continued to show higher levels of violence than their normative or nondisengaged peers. For chronic disengaged adolescents, moral disengagement could instead reflect a strategy of adaptation that is embedded into a system of beliefs about the self and others and leads to perceive aggression and violence as appropriate means to pursue one's own goals. Adolescents who consider aggression a morally acceptable behavior are more likely to act persistently aggressive (Crane-Ross, Tisak, & Tisak, 1998; Huesmann & Guerra, 1997; Keltikangas-Järvinen, 2001) and to avoid affective self-evaluative reactions like guilt (Bandura, 1991;

Bandura et al., 1996). Profile analysis demonstrated that at ages 14 and 16, the chronic group showed the same level of need for reparation as did the normative and the later desister groups. With increasing age, the chronic group decreased their level of need for reparation, whereas the later desister group continued to show the same level as the normative group. These results highlight how affective self-evaluative reactions were associated with different moral disengagement trends. The need for reparation associated with the negative outcomes of guilt-eliciting actions indicated that self-sanctions even existed at age 14, especially for the low disengaged group. During the course of adolescence, the chronic recourse to moral disengagement mechanisms consented people to attenuate self-sanctions and guilt feelings.

In accordance with previous findings (Bandura, 1999, 2004; Bandura et al., 1996), boys showed higher levels of moral disengagement than did girls and a lower decline from ages 14 to 16. Furthermore, adolescents in the chronic group were mostly boys, whereas most of nondisengaged group were girls. Several studies have attested that girls have higher moral emotional competence than boys (Eisenberg, 2000; Ferguson & Crowley, 1997; Lennon & Eisenberg, 1987; Mills, Pedersen, & Grusec, 1989) and lower levels of moral disengagement (Bandura, 2004; Bandura et al., 1996; Pelton et al., 2004) and aggressive behaviors (Bettencourt & Miller, 1996; Knight, Guthrie, Page, & Fabes, 2002). Furthermore, results showed that boys evaluated as aggressive by their peers already in early adolescence were more at risk to recourse to moral disengagement than girls. Moreover, both boys and girls that were never nominated by their classmates had a higher probability of being a member of both the normative and the nondisengaged groups. Thus, it is more probable that adolescents, especially boys, who have already shown aggressive behaviors in early adolescence, have more opportunities to recourse to moral disengagement.

Regarding the outcomes, the stability and change of moral disengagement significantly affected aggressive and violent behaviors. In fact, on the one hand, decreasing levels of moral disengagement at the population level were significantly linked with lower levels of physical and verbal aggression and violence in late adolescence. On the other hand, the analysis of the predictive power of moral disengagement trajectories showed that different trends were differently associated with aggressive and violent outcomes. For the nondisengaged youth (above all girls), the decline over time was negatively associated with aggressive and violent behavior. Instead, for the later desister youth, which were more likely to be at risk, the decline over time was not significantly associated with aggressive and violent outcomes. In this last case (7% of total sample), we cannot exclude the beneficial effect due to a later development of social emotional skills. For the chronic group, who showed high stable levels of moral disengagement over the course of time and the lowest levels of self-sanction for their offensive behaviors in late adolescence, the relation between moral disengagement development and aggressive and violent outcomes was particularly problematic. In fact, the results indicated that adolescents with a high probability of being a member of this group were more likely to show frequent aggressive and violent behavior in late adolescence, controlling for gender and peer nomination of physical and verbal aggression at age 12. For these youth, the stable tendency toward moral disengagement may reflect a crystallization of moral disengagement mechanisms over time that subsequently legitimatizes the recourse to aggressive and violent behaviors. The influence that moral disengagement exerted on engagement in aggression and violent episodes for these adolescence (above boys) calls one's attention to the psychological processes and social models that provide the cognitive framework within which retaliation, revenge, and violence appear appropriate and acquire legitimacy (Arsenio & Lemerise, 2004; Caprara, 1996).

In sum, the longitudinal findings of the present study indicated that: (a) most adolescents exhibited declining levels of moral disengagement over time; (b) adolescents who exhibited lower levels of moral disengagement than the normative group were typically girls, less likely to show aggression and violent acts in late adolescence and more likely to feel guilt; (c) adolescents who showed high levels of aggression in early adolescence were more likely to recourse to moral disengagement; (d) adolescents who maintained higher levels of moral disengagement were typically boys, were more likely to show frequent physical and verbal aggression and violent acts, and were less likely to feel guilt in late adolescence; and (e) adolescents who were more likely to exhibit aggression and violent acts in late adolescence were typically boys evaluated as aggressive by peers in early adolescence.

Limitations and Future Directions

The identification of developmental pathways of moral disengagement represents a first step in understanding the processes that drive some people to resort to aggression and violence more frequently than others in late adolescence. However, clarification of some issues remains necessary. First, our findings call for some caution in light of the possible limitations of the study due to the specific cultural context where the research was conducted and the use of self-report data. Second, because there are different approaches in studying moral development, future research should combine the study of moral disengagement (see Bandura, 1991) with the examination of moral reasoning and moral judgments (Kochanska & Aksan, 2006; Yau & Smetana, 2003) over the course of development. Third, future studies should examine the role of self-evaluative reactions in preventing the chronic recourse to moral disengagement mechanisms that may get crystallized over time. In this respect, different studies have highlighted the importance of studying affective reactions such as guilt, remorse, and empathy in association with moral development (Eisenberg, 2000; Hoffman, 1979; Kochanska & Aksan, 2006; Tangney et al., 2007). Finally, further studies should clarify how differences in moral disengagement are associated with emotional, cognitive, and social processes implied in moral self-regulation (Hart & Carlo, 2005; Turiel, 2006) and how individual skills and environmental factors could affect both individual differences and aggressive and violent outcomes. In this regard, we believe that it is necessary to combine the systematic study of individual differences with the study of external situational variables within a longitudinal perspective. The study of both internal mechanisms and relevant environmental variables that operate at stimulus, social, contextual, structural, and cultural levels to influence individual, and group behaviors are necessary in designing appropriate interventions aimed at preventing aggressive and violent outcomes.

Appendix

Moral Disengagement Scale

1. It is alright to fly off the handle to protect your friends.
2. Slapping and shoving someone is just a way of joking.
3. Damaging some property is no big deal when you consider that others are beating people up.
4. A member of a group should not be blamed for trouble the group causes.
5. If youth are living under bad conditions in their neighbourhood they cannot be blamed for behaving aggressively.
6. It is not serious to tell small lies because they don't hurt anybody.
7. Some people deserve to be treated like animals.
8. If people fight and misbehave in school or at work it is their teacher's /superior's fault.
9. It is alright to beat someone who bad mouths your family.
10. To hit obnoxious friends is just giving them "a lesson."
11. Stealing some money is not too serious compared to those who steal a lot of money.
12. A person who only suggests breaking rules should not be blamed if others go ahead and do it.
13. If youth are not disciplined at home they should not be blamed for misbehaving.
14. People do not mind being teased because it shows interest in them.
15. It is okay to treat somebody badly who behaved like a "worm."
16. If people are careless about where they leave their things it is their own fault if they get stolen.
17. It is alright to fight when your group's honour is threatened.
18. Taking someone's motorcycle or car without their permission is just "borrowing it."
19. It is not serious to insult a friend because beating him/her up is worse.
20. If a group decides together to do something harmful it is unfair to blame a single member of the group for it.
21. Youths cannot be blamed for using bad words when all their friends do it.

22. Teasing someone does not really hurt him/her.
23. Someone who is detestable does not deserve to be treated like a human being.
24. People who get mistreated usually do things that deserve it.
25. It is alright to lie to keep your friends out of trouble.
26. It is not a bad thing to "get drunk" once in a while.
27. Compared to the illegal things people do, taking some things from a store without paying for them is not very serious.
28. It is unfair to blame a single person who had only a small part in the harm caused by a group.
29. Youth cannot be blamed for misbehaving if their friends pressured them to do it.
30. Insults among peers do not hurt anyone.
31. Some people have to be treated roughly because they lack feelings that can be hurt.
32. Youths are not at fault for misbehaving if their parents are too restrictive (severe, and they don't allow them any freedom).

The following items correspond to the various mechanisms of moral disengagement. *Moral justification*: 1, 9, 17, 25. *Euphemistic language*: 2, 10, 18, 26. *Advantageous comparison*: 3, 11, 19, 27. *Displacement of responsibility*: 5, 13, 21, 29. *Diffusion of responsibility*: 4, 12, 20, 28. *Distorting consequences*: 6, 14, 22, 30. *Attribution of blame*: 8, 16, 24, 32. *Dehumanization*: 7, 15, 23, 31.

Arguing on the Computer: A Microgenetic Study of Developing Argument Skills in a Computer-Supported Environment

Deanna Kuhn, Wendy Goh, Kalypso Iordanou, and David Shaenfield
Columbia University

We report a study of a class of 28 sixth graders engaged in an extended computer-supported argumentive discourse activity. Participants collaborated with a same-side peer in arguing against successive pairs of peers on the opposing side of an issue. Meta-level awareness was facilitated by conducting the dialogs via instant messaging software, which made available a transcript of the dialog that was used in additional reflective activities. In the course of dialogs on 3 successive topics, participants showed significant gains in meta-level communications about the discourse, reflecting at least implicit understanding of its goals, as well as in the strategic moves that constituted the discourse. The latter advances remained evident when the social support of a same-side partner was withdrawn.

The central place of argument skills in the development of higher order thinking is increasingly being recognized. Indeed, the construction and evaluation of arguments constitute a major component of the College Learning Assessment (Hersh, 2005), designed to assess the cognitive development that occurs during the college years. Until recently, research on argument skills has been devoted almost entirely to individuals' written or verbal arguments in support of a claim. Studies have been consistent in revealing skills that are at best modest among children and adolescents and show little improvement thereafter (Brem & Rips, 2000; Glassner, Weinstock, & Neuman, 2005; Kuhn, 1991; Means & Voss, 1996; Perkins, 1985; Stanovich, 1999; Voss & Means, 1991; Weinstock, Neuman, & Tabak, 2004).

The work presented here is part of a growing body of research that examines the process of argumentation, or argumentive discourse, in older children and adolescents (Voss, 2001). As elaborated elsewhere (Graff, 2003; Kuhn, 2005), such discourse is of interest for its alleged role in facilitating the development of individual (nonsocial) argument skills. We agree with Graff's (2003) view that dialogic argument provides the "missing interlocutor" that lends purpose to and thereby facilitates development of individual argument skills.

Although competence in individual argument skills is clearly critical, most notably in academic contexts, the development of dialogic argumentation skills is important in its own right. What needs to develop in the domain of argumentive discourse skill and how does this development occur? The present work is focused on these questions, although we include an assessment of the extent to which gains observed in argumentive discourse affect performance on a measure of individual argument.

Dialogic argumentation has long been of broad interest to developmentalists, particularly those who regard social collaboration as central to cognitive development (Damon, 1984; Moshman, 2005; Smetana, Killen, & Turiel, 1991; Wainryb, Shaw, Laupa, & Smith, 2001). The focus of more recent, educationally oriented research on argumentive discourse has been on devising scaffolds (typically computer software) to support the argumentation process (Andriessen, 2006; Andriessen, Baker, & Suthers, 2004; Bell & Linn, 2000; Chinn, 2006; Clark & Sampson, 2005; Glassner & Schwarz, 2005; Nussbaum, 2005; Wiley & Voss, 1999; Zohar & Nemet, 2002). The work of Anderson and colleagues (Anderson et al., 2001; Reznitskaya et al., 2001) and, following them, Nussbaum (2003) is an exception in examining naturally occurring discourse in small groups of elementary-school-age children and seeking to identify the roots of more sophisticated argumentation skills as they emerge in such conversation and spread from one child to others.

Dialogic argument is a skill that has the advantage of early roots in everyday conversation, and yet, the demands of skilled argumentive discourse are considerable, with previous research indicating that few individuals attain proficiency during the second decade of life (Felton & Kuhn, 2001; Kuhn & Franklin, 2006; Kuhn & Udell, 2003; Udell, 2007). At the same time that one is processing and evaluating input from the conversational partner, one must be formulating

an effective response that meets discourse goals. According to Walton (1989), skilled argumentation has two goals. One is to secure commitments from the opponent that can be used to support one's own argument. The other is to undermine the opponent's position by identifying and challenging weaknesses in his or her argument. Both these goals, note, require attention to the opponent's claims.

In earlier work, we have found that young adolescents concentrate their efforts on exposition of their own claims to the neglect of attending to the opponent's claims and attempting to weaken their force (Felton, 2004; Felton & Kuhn, 2001; Kuhn & Udell, 2003; Udell, 2007). Yet, they are able to attend to the other's argument, we have found, and even generate an argument against it, when explicitly instructed to do so (Kuhn & Udell, 2007). The challenge, then, may be less one of executing the skill (of addressing the opposing position) than it is one of recognizing the need to do so. This recognition goes to the very heart of argument. If the opponent's argument for his or her position is not relevant, the process through which one may claim to attain victory over the opponent cannot be regarded as one of argument.

In the present work, we focus on how young adolescents develop better meta-level understanding of the goals of argument, as well as procedural skill in implementing these goals in discourse. Our prior work indicates that dense engagement over time in argumentive discourse with a series of peers does lead to advancements in procedural skill, and we seek to corroborate this finding in the present study. Our focus here, however, is on the development of meta-level understanding about argumentive discourse and its goals. Specifically, does this meta-level understanding also develop and support skill development at the procedural level, that is, in the strategies involved in the actual conduct of the argumentation?

Most generally, one must see a point to argument if one is to engage in it effectively (Kuhn, 1991, 2005). Specifically, we claim, one must understand the goal of argumentation as one of engaging one another's claims and undertaking to weaken them, as well as seeking acceptance of one's own claims—the two goals noted earlier identified by Walton (1989). Progress with respect to this meta-level development, we propose, is likely to support progress in the procedural aspect as well.

The form of dense engagement in peer discourse devised for this study was designed with the objective of supporting to the extent possible the meta-level, as well as strategic, development to which we have referred. Beyond dense engagement in discourse itself, which has been found effective with various age groups in our own previous studies (Felton, 2004; Felton & Kuhn, 2001; Kuhn, Shaw, & Felton, 1997; Kuhn & Udell, 2003; Udell, 2007) and those of several other researchers (Anderson et al., 2001; Chinn, 2006; Nussbaum, 2003; Nussbaum & Kardash, 2005; Nussbaum & Sinatra, 2003; Reznitskaya et al., 2001; Schwarz, Newman, & Biezuner, 2000), the general strategy we thought might be most effective is to heighten participants' awareness of the discourse. This meta-level awareness regarding the discourse seems a necessary condition to formulating, and ultimately implementing, goals with respect to it.

We employ three techniques designed to heighten and support this awareness. First, we ask participants to work in pairs. The two members of the pair hold the same position on an issue and they collaborate in arguments against a series of opposing pairs who hold the opposite position. Each communication to the opposing dyad is made only when the pair has agreed what it is to be. Having to deliberate regarding each argumentive move, we hypothesized, would not only generate more thoughtful contributions to the discourse but also make the collaborative pair more aware and reflective regarding this discourse.

The second technique, following on the study by Felton (2004), is to integrate an explicit reflective activity into the series of dialogs. In the present study, we do this by making available to participants some of their own dialog transcripts as the basis for this activity. Support for these design features comes from the study by Felton; although adolescents individually engaged in argument with an opposing peer, two peer advisors observed and later discussed possible improvements with their partners—a condition Felton found enhanced dialogic argument skills relative to a condition in which participants argued without peer advisors. In the present study, we engage peers in collaboratively planning and implementing the exchange itself, not only reflecting on it.

The third technique we employ here is to conduct these dialogs via computer-supported instant messaging (IM) software, a method we have not tried in previous work and the one that constitutes the major innovation of the present study. In addition to capitalizing on young teens' familiarity with the medium, this technique has the benefit of providing an immediately available and permanent record of the discourse, in striking contrast to the conditions of real-time verbal discourse, where the contents of each contribution to the dialog immediately disappear as soon as they are spoken.

The present study extends over an entire school year. We begin with assessments of individuals' argument skills, both in generating an individual written argument in support of their position on a social issue and in engaging in an electronically conducted argument with a peer who holds an opposing view on the topic. These assessments are repeated at the end of the year, allowing us to assess improvement in both individual and dialogic argument skills. A focus of our work, however, is microgenetic analysis (Kuhn, 1995; Miller & Coyle, 1999; Siegler, 2006) of the period of intervention itself. During this time, we observe participants developing meta-level understanding of argumentation, as well as developing strategic skill in executing it, as each participant and a partner engage in electronic discourse with an opposing pair on a series of new topics.

Method

Participants

The 28 participants consisted of the entire sixth grade at a university-affiliated independent school in a large urban setting. The school has a unique population in that 50% of the school's slots are reserved for children of university faculty and high-level administrators, whereas the remaining 50% of slots are filled by children from the surrounding low- to middle-income community chosen by lottery and receiving full financial support. The school was in only its 2nd year of operation, the year that the work described here took place. Hence, students had come from a wide range of previous schools and were of diverse academic, as well as ethnic, racial, and socioeconomic, backgrounds. Roughly half were identifiable as racial or ethnic minorities (largely Hispanic and African American). All were 11 or 12 years of age; 16 were girls and 12 were boys.

Participants had become familiar with the school's innovative curriculum by the time our project began. The school features an integrated curriculum across all subjects and has a strong technology emphasis, with Smartboards in each classroom and students each allocated an individual laptop computer used daily in their schoolwork.

Initial Assessment

Capital punishment (CP) was the topic on which initial and final assessments of both individual and dialogic argument were based.

Individual argument. Each participant's initial position on CP was assessed using a 13-point Likert scale. The middle position on the scale read, "I have mixed or undecided opinions about capital punishment." Each position to one side or the other of this middle point represents a position progressively more extreme in support of or against CP. The Point 1 position from the center on the "support" end of the scale, for example, read, "I am somewhat in favor of CP but I'm not sure," whereas the end position read, "I am totally in favor of CP. I will never change my opinion and I cannot imagine how someone could have a different opinion." Prior to asking participants to check a box that best represented their view, one of the adult coaches defined CP for the class ("administering the death penalty for serious crimes such as murder") and explained the scale.

Completion of the scale instrument was followed by a written assessment instrument. After again eliciting the participant's position as for, against, or undecided, the following questions were posed (with space after each for the participant to respond):

1. Why did you choose this position? In other words, what are your reasons for your position?
2. What are some other possible reasons for this position? These reasons can be your own reasons or other people's reasons who have the same position as you.
3. Can you imagine someone having another position that is different from your own? What would it be?
4. What might be some reasons for having this different position?
5. Can you think of any other reasons to be for or against CP?

Dialogic argument. The 8 participants who indicated they were undecided on the scale gave reasons on both sides of the issue in the questionnaire. These 8 were grouped with the 6 participants who chose a scale position supportive of CP. The remaining 14 participants, who indicated they were opposed to CP on both the scale and the questionnaire, formed a second group. The week following the individual assessment, each of the participants from Group 1 was paired with a participant from Group 2, and each of these pairs was asked to participate in a dialog with one another on the topic of CP.

To conduct these dialogs, all Group 1 members were situated in one classroom and all Group 2 members in an adjacent classroom. Dialogs were conducted via *FirstClass*© IM software, installed on each participant's individual laptop computer. Partners were instructed to conduct a dialog via IM. Their goal, they were instructed, was to try to convince their partners that their position was the better one. These dialogs lasted from 10 to 20 min; they ended when participants indicated they had finished or when no more time was available. The software saved the dialog for analysis.

Intervention: Collaborative Dialogic Argument Plus Reflection

The argumentation activity took place in three identical phases, each devoted to a different topic. The first of the three phases, described here in detail for illustration, comprised thirteen 40-min classroom sessions occurring twice per week. The activity was introduced to students as a class in learning to become good arguers. The class project was to focus on ColumbiaTown, a new town being formed in the middle United States. The governing board of the new town had to establish rules and laws for the new town, and in particular, the participants' task would be to focus on the new school that was being formed to serve the town's children. The first topic was to be whether attendance at school should be mandatory for all children in the town. Specifically, the following dilemma was introduced:

> The Costa family has moved to the edge of town from far away Greece with their 11-year-old son Nick. Nick was a good student and soccer player back home in Greece. Nick's parents have decided that in this new place, they want to keep Nick at home with them, and not have him be at the school with the other children. The family speaks only Greek, and they think Nick will do better if he sticks to his family's language and doesn't try to learn English. They say they can teach him everything he needs at home.
>
> What should happen? Is it okay for the Costa family to live in the town but keep Nick at home, or should they be required to send their son to the town school like all the other families do?

Phase 1 individual assessment. The positions of all participants on this topic were elicited via an individual written questionnaire. The questionnaire asked the participant to indicate their position among the three options, "Nick should go to the school," "Nick can be taught at home," and "undecided." Participants were then asked to indicate how certain they were of their positions on a 6-point scale ranging from *certain* to *not sure at all.* The questionnaire then proceeded to pose the same sequence of probing questions described earlier for the CP-topic individual assessment.

Phase 1 dialogic engagement. Based on responses in the individual assessment, two groups of 14 students each were formed, one group who chose the homeschool option and another group who either chose mandatory townschool ($n = 9$) or were undecided but noted reasons supporting the townschool side ($n = 5$). Within each of the groups, homeschool and townschool, same-gender pairs were formed. To the extent possible, an additional criterion used in forming these pairs was to pair participants who provided different reasons for the same position.

The same-side pairs thus formed remained together until the "showdown" segment (see below) of Phase 1. Beginning at the next class session, pairs in one group assembled in one classroom and pairs in the other group assembled in an adjacent classroom. Each pair was assigned to conduct a dialog via IM with a pair from the other room. Their goal, they were instructed, was to try to convince the other pair that their position was the better one. Each pair was further instructed to collaborate with their partner to decide what they wished to say to the opposing pair and, once they were in agreement, to type their response and send it to the opposing pair.

Those in one room were arbitrarily chosen to begin the dialogs by stating and supporting their position, with the pairs in the other room then given the opportunity to respond. Each of the pairs in one room thus continued their dialogs with one of the pairs in the other room, with dialogs lasting an average of 25 min. At the next session, each pair conducted a dialog with a different opposing pair, until each pair had debated every opposing pair—a total of seven sessions. One or two adult coaches circulated each room during these sessions, answering any questions and reminding pairs to collaborate with one another in deciding what response to make.

Participants received no explicit instruction with respect to argumentation. The only exception, used occasionally if it appeared in danger of being violated, was to "criticize ideas, not people." The only implicit instruction was the invoking of a metaphor expressed occasionally to the whole group that in responding they should strive to "get the ball over the net and back to the other side."

Phase 1 reflective activity. After four of the seven dialog sessions had been completed, the first reflective activity was introduced at the next session. At these sessions, each pair was given a printed transcript of the preceding session's dialog. (Because sessions took place twice a week, the interval between the dialogic session and the reflective session was 3–4 days.)

In the reflective session, in addition to the transcript of the preceding session, pairs were given one of two scaffold sheets. The "Other's Argument" scaffold sheet prompted pairs to examine the opposing pair's argument and their own counterargument. The "Own Argument" scaffold sheet prompted pairs to examine the opponent's counterargument and their own rebuttal to this counterargument. In each case, they were asked to contemplate what a better counterargument or rebuttal might have been. The adult coaches circulated during these sessions to provide clarifications if needed.

Reflective sessions took place a total of three times during Phase 1, interspersed among the dialog sessions. Specifically, the first Other's Argument session occurred after the fourth dialogic session, the first Own Argument session occurred after the fifth dialogic session, and a combined reflective session in which both scaffold sheets were available occurred after the sixth dialogic session.

Phase 1 preparation and showdown. Following the seven dialogic and three reflective sessions, participants were told at the next session that it was time to begin preparation for a final showdown debate with the opposing side. They were given one session to prepare for the showdown and the following session to conduct it.

To prepare, pairs within their opposing-sides classrooms were regrouped into an A and a B team. One team was encouraged to become "own argument" specialists by reviewing the possible counterarguments the opposition would make to their arguments and the rebuttals they would have ready. The other team was encouraged to become "other argument" specialists by reviewing the possible arguments the opposition would make and the counterarguments they would have ready. Transcripts of the dialogs, the previously completed scaffold sheets, and blank index cards were made available.

For the showdown, the two opposing groups remained in their respective classrooms and communicated with one another via the same IM software but this time with a single computer terminal and Smartboard in each room. To conduct the showdown, students were again reorganized, this time into Team A and Team B (each containing similar numbers of "own argument" and "other argument" specialists), with Team A allocated to be the acting team for the first half of the activity (with Team B advising by transmitting suggestion cards to the acting team), and the roles reversed for the second half of the activity. The entire activity lasted 50 min.

At the session following the showdown, an argument map that had been prepared by the researchers was presented to the assembled class. Different colors, as well as labels, were used to identify argumentive moves as effective (green), less effective or ineffective (red), and neutral (blue or black). A point system was applied to this map, making it possible to declare a winning team.

Phases 2 and 3. Phase 2 began following winter vacation and Phase 3 following spring vacation. Phases 2 and 3 proceeded in an identical way to Phase 1 except for new topics and a slight reduction in number of sessions (one less dialogic and one less reflection session) due to the slightly reduced time available in the school calendar for these two phases.

The topic for Phase 2 was whether students who continually disrupt the classroom should be expelled or allowed to remain. The topic for Phase 3 was whether teachers should receive experience-based pay (with more experienced teachers more highly paid) or all teachers should receive the same pay.

Final Assessment

The final assessment occurred following Phase 3. It was on the same (CP) topic and contained the same components as the initial assessment. In the dialogic activity, all participants argued with the same opponents they had engaged in the initial assessment.

Results

We begin analysis with a comparison of participants' performance on initial and final assessments. This analysis allows us to establish the overall progress in skills that each participant made, assessed in a content domain different from the ones involved in the intervention. In addition to its importance in its own right, this information proves useful in examining progress during the intervention itself. Our initial analytic task, however, before microgenetic examination could begin, was to apply a common dialogic coding scheme to the initial and final dialogs, as well as to the intervention dialogs.

Coding of Electronic Discourse

Each of the 161 electronic dialogs (7 per session at 19 intervention sessions across the three intervention topics and 14 each at the initial and final assessments) was analyzed based on an elaborated version of the scheme used in earlier research (see Felton, 2004; Felton & Kuhn, 2001; Kuhn & Udell, 2003; Udell, 2007). The discourse is segmented into idea units and a code assigned to each unit based on its functional relation to the opponent's immediately preceding utterance in the dialog. Coders blind to the identity of participants or time of the dialog took part in the coding. Interrater reliability (calculated on a randomly chosen 15% of the intervention dialogs and 100% of the initial and final dialogs, all of which were double coded) indices were 89% agreement on individual units within dialogs and a Cohen's kappa of .87. Coding reliability was examined individually for each of the major categories to be examined here and was found to be in a comparable range. The percent agreement for the Counter-C category (see definition below), for example, was 98% with a Cohen's kappa of .89. An additional coding scheme for meta-level discourse was developed to aid in examination of the intervention dialogs and will be described in presenting the intervention data analysis.

Skills at Initial and Final Assessments

At the initial assessment, dialogs contained a mean of 14.94 coded utterances ($SD = 8.26$). At the final assessment, dialogs contained a mean of 15.06 utterances ($SD = 8.12$), a nonsignificant difference. Mean number of words contained in each utterance increased, however, from 6.83 ($SD = 2.57$) at the initial assessment to 11.70 ($SD = 4.44$) at the final assessment—a significant increase, $F(1, 54) = 25.28$ ($p < .001$).

In comparing the kinds of utterances contained in dialogs at the two assessment times, only those categories from the coding scheme are examined that accounted for greater than 5% of utterances, averaged across dialogs, by the time of the final assessment. These categories are Clarify, Case?, Counter-A, and Counter-C. Percent use of each of the other categories was 5% or below at one or both assessment points. (Meta-level categories are addressed later.) In the comparisons across time reported below, an arcsine transformation was performed to normalize proportions.

Counterargument (Counter-A and Counter-C). Counterargument is the central and most essential skill to be mastered if one is to engage in effective argumentive discourse. Its use reflects awareness of the dual goals of argumentive discourse noted earlier (to weaken the opponent's argument, as well as to gain concessions from the opponent that will support one's own argument). We assess the use of two forms of counterargument. The weaker form, Counter-A (counter-alternative), addresses the other's position and undertakes to reduce its force, but it does so by introducing a new criticism of the other's position, not directly related to the argument the other has just made in support of his or her claim. The stronger, more skilled form of counterargument, Counter-C (counter-critique), by contrast, directly addresses the other's argument, criticizing it in a way that seeks to weaken its force. In the case of the CP topic, for example, if the other's argument is "CP will keep dangerous criminals off the street," a common Counter-C is "Life imprisonment can do that as well," whereas a common Counter-A is "Sometimes innocent people are executed."

In analyzing change in counterargument usage from initial to final dialogs, we examined three indices of counterargument skill. The first is the proportion of utterances a participant made that were counterarguments of either type. The second is the proportion of utterances that were coded as Counter-Cs. The third is the proportion of utterances coded as counterarguments that were Counter-Cs. Thus, we look both at mastery of counterargument itself and then at indications of the extent to which counterarguments are being used most effectively.

All three of these indices showed significant increases from initial to final assessments. The percentages were transformed using an arcsine transformation. Overall Counter usage increased from an average of 6.34% ($SD = 7.66$) of utterances at the initial assessment to 26.53% ($SD = 17.27$) at the final assessment, a significant change over time, $F(1, 27) = 31.75$, $p < .001$, $\eta_p^2 = .540$. Counter-C usage increased from 4.50% ($SD = 7.09$) to 21.37% ($SD = 14.61$), $F(1, 27) = 19.89$, $p < .001$, $\eta_p^2 = .424$. Finally, the percentage of Counters that were Counter-Cs increased from 31.25% ($SD = 45.45$) to 63.79% ($SD = 37.75$), $F(1, 27) = 7.27$, $p = .012$, $\eta_p^2 = .212$.

As important as these group trends are patterns of individual change, especially as we wish to relate such patterns to patterns of individual change that participants show during the intervention itself. At the initial assessment, only 36%—10 of 28—participants made any Counter-C arguments. At the final assessment, all but one did so (a significant change, McNemar test, $p < .001$). At the initial assessment, 50% (14 of 28) participants made *any* counterarguments at all, but all did so at the final assessment (also a significant change, $p < .001$).

Also of interest are the proportions of participants who showed increases in their overall Counter and Counter-C arguments from initial to final assessments—a majority did so, 85% in the case of overall Counters and 78% in the case of Counter-Cs. Only 1 participant showed no Counter-C usage at either assessment. Of the remaining participants who failed to show improvement in Counter-C usage, all showed some slight usage at each assessment.

Rebuttal. A further important aspect of counterargument is the extent to which discourse participants are able to maintain focus and consistency in intent and execution that enables them to sustain the critique of one another's arguments. Once the initiator of a claim responds to an opponent's counterargument by countering this counterargument, we have what is commonly referred to as a rebuttal. In our analyses of participants' dialogs, we looked at both frequency of rebuttals and length of rebuttal strings, that is, over how many contributions to the dialog a sequence of Counters is maintained.

Participants in the present study showed little initial skill in rebuttal. Only 6 of 28 (21%) made any rebuttal utterances at the initial assessment. At the final assessment, this number increased to 19 (68%)—a threefold and significant increase ($p < .001$). Consistent with this increase, mean number of rebuttals across participants increased significantly from 0.39 ($SD = 0.88$) at the initial assessment to 1.82 ($SD = 2.06$) at the final assessment, $F(1, 26) = 10.51$, $p = .003$. Overall frequencies are presented in this case, rather than percent usage, because production of rebuttals is affected by the opportunities available to make them. In other words, a participant cannot make a rebuttal if the opponent has made no counterargument. We therefore also calculated the percentage of rebuttal opportunities that were taken advantage of, that is, the number of rebuttals an individual made relative to the number of opportunities for rebuttal offered by the opponent. This percentage increased from an average of 17.65% ($SD = 35.15$) at the initial assessment to 43.79% ($SD = 36.48$) at the final assessment. This change, note, however, is confined to a reduced sample, the 12 participants who had any opportunities for rebuttal at the initial assessment (all did so at the final assessment), and this sample size is not large enough for statistical test. Interpretation of group data on increasing rebuttal skill thus remains limited until counterargument skill reaches a level at which all participants have available numerous opportunities to make rebuttals.

We looked finally at the length of rebuttal strings, whenever rebuttals were made. A length of 1 represents a sequence consisting of assertion – counterargument – counterargument; a length of 2 represents a sequence consisting of assertion – counterargument – counterargument – counterargument. Mean length rose only slightly from 1.83 at the initial assessment to 2.13 at the final assessment (a statistically nonsignificant increase). These numbers show a typical successful effort on the part of a maker of an initial counterargument to not allow to stand as successful the opponent's move to weaken this counterargument (length of 2, i.e., assertion – counter – counter – counter).

Exposition (Clarify and Case?). Clarify, the most common utterance category, includes all those utterances in which the participant asserts or elaborates his or her own arguments. Although in previous work (Kuhn & Udell, 2003) usage in this category has declined as counterargument usage increased, participants in the present study overall showed a constant percent usage of Clarify—an average of 21.6% ($SD = 10.1\%$) at the initial assessment and 21.7% ($SD = 14.2\%$) at the final assessment. Because overall length of dialogs (reflected in number of utterances) remained constant, as reported earlier, this finding indicates absence of change in either number or proportion of utterances in the Clarify category.

Case? is another category that in past research has shown different patterns of change in different samples, with the suggestion that its use may increase temporarily but then diminish as other argument strategies become available (Felton, 2004; Felton & Kuhn, 2001). In Case?, the participant poses a situation to the other and asks the other to respond. In discussing the CP topic, for example, one member of the dyad might ask the other how she would feel about CP if the murder victim were a family member. The use of Case? is effective when it poses the situation with the intent of securing concessions from the other and in this respect may be seen as a stepping stone or alternative to direct counterargument. In the present analysis, the average percent use of Case? increased from 1.54% ($SD = 3.10$) at the initial assessment to 6.84% ($SD = 11.68$) at the final assessment, $F(1, 27) = 13.18$, $p = .001$, $\eta_p^2 = .328$.

Individual Argument

Although our purpose in the present work is to examine the development of dialogic argument skills in their own right, we did obtain evidence that increasing dialogic skill leads to improvements in individual (nondialogic) argument. Such evidence corroborates our own and others' earlier studies of individual argument skills (Kuhn, Shaw, & Felton, 1997; Reznitskaya et al., 2001) in which such positive effects of practice in dialogic argument on individual argument have been observed (allegedly due to enhanced awareness of the "missing interlocutor" implicit in nondialogic arguments).

The coding scheme developed by Kuhn et al. (1997) was used for assessment of individual CP arguments. In particular, we examined the quality, quantity, and sidedness (two- vs. one-sided) of initial and final individual arguments for or against CP. As 1 participant was away for medical reasons at the final individual assessment, these analyses are based on a sample size of 27. Level 1 reasons in this scheme offer genuine justifications for or against the use of CP, whereas Level 2 reasons offer only functional arguments regarding the criteria for use or nonuse of CP (e.g., "only if it's a serious crime"), without addressing justification of the practice itself, and Level 3 reasons are entirely nonjustificatory (e.g., appeal to precedent or authority). (See Kuhn et al., 1997, for the full scheme.)

At the initial assessment, a mean of 0.56 (*SD* = 0.93) different Level 1 reasons were produced compared to a mean of 1.33 (*SD* = 1.00) at the final assessment—a significant increase, *t*(26) = 2.95, *p* = .007. (Repetitions of the same argument code did not increase an individual's score.) Of the 27 participants, 25 added at least one new Level 1 reason at the final assessment. Total number of different reasons (of all levels) increased from a mean of 3.07 (*SD* = 1.59) to a mean of 4.22 (*SD* = 1.80)—a significant increase, *t*(26) = 2.37, *p* = .026. The number of participants producing two-sided arguments (citing reasons both for and against CP), either initially or when elicited ("Can you imagine someone having another position that is different from your own? What would it be?") increased from 17 to 22 across the two assessments.

Dialogic Skill Development During the Intervention

Analysis of the discourse patterns during the three phases of the intervention is based on a sample size of 28. We divide the presentation of results into two sections, the first section reporting on trends in discourse performance itself and the second section examining trends in the use of meta-level discourse that seeks to evaluate, question, monitor, direct, or otherwise manage this performance.

Overall patterns of change at the group level. For these analyses, the dialog sessions for each topic were collapsed into beginning, middle, and final segments (with two sessions combined in each category except for the middle category for Topic 1, which included three sessions). A participant received the same score as his or her (same-side) partner for a particular session (and the pair taken as the unit of analysis where appropriate in statistical analyses). Dialogic sessions remained fairly stable over time with respect to length. Mean number of utterances per session were 42.12 (*SD* = 8.22) for Topic 1, 37.36 (*SD* = 9.21) for Topic 2, and 42.71 (*SD* = 10.80) for Topic 3. Mean length of utterances increased only slightly from 8.11 (*SD* = 6.17) for Topic 1 to 9.55 (*SD* = 8.10) for Topic 2 and 9.17 (8.52) for Topic 3. Mean word length is overall higher, however, for the Counter-C category, a major focus of our interest, and increased across topics, from 11.29 (*SD* = 6.85) for Topic 1 to 13.75 (*SD* = 8.61) for Topic 2 to 15.74 (*SD* = 9.45) for Topic 3.

Counterargument. In Table 1, there appear the mean percentages of all utterances that were coded as Counter (top row) or Counter-C (second row). The final row shows the mean percentages of Counters that were coded as Counter-C. As reflected in the leftmost column (beginning of Topic 1), the mean percentage of utterances that a participant devotes to counterargument increases substantially, to 24.43%, from the earlier reported mean level of 6.34% at the initial (CP) assessment, where participants argued alone against their opponent rather than with a partner as they do here. Similarly, the mean percentage of Counter-Cs increased from the initial CP assessment, from the earlier reported 4.50% when working alone to the 13.87% shown here. These changes are suggestive of the advantages provided by collaboration with a partner as well as what we have observed in past work to be the motivating and focusing effects of working toward the social objective of the showdown.

As seen in Table 1, however, performance continues to improve during Topic 1 but does not increase further in these respects after the first topic. Based on pairs as the unit of analysis, for Topic 1, gains (from beginning to end) are significant for overall Counters, Z = −2.605 (Wilcoxon test), *p* = .009, effect size *r* = −.696, and for Counter-Cs, Z = −2.166, *p* = .03, effect size *r* = −.579. For Topic 2, gains are significant only for Counter-Cs, Z = −2.355, *p* = .019, effect size *r* = −.629 (for overall Counters, Z = −1.789, *p* = .074), and for Topic 3, no trends over time are significant (Counter-C: Z = −0.722, *p* = .470; overall Counters: Z = −0.659, *p* = .510). Note finally that when we

Table 1
Mean Percent Usage of Counterargument and Counterargument-Critique (Counter-C) Across the Three Topics

	Topic 1		Topic 2		Topic 3	
	Beginning	End	Beginning	End	Beginning	End
Total Counters	24.43 (8.50)	32.30 (10.49)	16.19 (5.80)	20.77 (8.55)	20.15 (8.98)	18.70 (8.17)
Counter-C	13.87 (4.89)	20.62 (9.49)	9.28 (4.99)	14.31 (8.17)	10.37 (5.74)	9.32 (7.75)
Percentage of Counters that are Counter-C	58.22 (15.26)	63.30 (17.07)	57.29 (29.52)	61.16 (25.28)	50.64 (27.35)	48.23 (29.02)

Note. Standard deviations appear in parentheses.

compare the percentages in Table 1 to those for the final CP assessment reported earlier (26.53% for Counters and 21.37% for Counter-Cs), it is apparent that gains made during the intervention are maintained when participants return to dialogic arguments against an opponent without the aid of a collaborative partner.

Rebuttal. We do not undertake statistical analysis of changes in percentage of rebuttal opportunities successfully met due to the initial scarcity and only gradual increase in the availability of such opportunities over time, as noted earlier in the report of rebuttal usage at initial and final (CP) assessments. By the time of the third intervention topic, however, rebuttal skill had been attained to the extent that all pairs showed some rebuttal usage during this topic and 41.52% of rebuttal opportunities were successfully taken advantage of (with all participants having such opportunities)—a percentage comparable to the 43.79% noted earlier observed at the final (CP) assessment. The mean length of Topic 3 rebuttal chains was 2.03 (range = 1–7) comparable to the 2.13 (range = 1–5) observed at the final (CP) assessment. An example of a successful rebuttal chain (of Length 2) is presented in Table 2 for Topic 3 (teacher pay).

Individual change patterns. Although the preceding results are suggestive, they do not tell us to what extent individual patterns of performance conform to group trends portrayed in Table 1. For this purpose, we looked at individual change patterns. We focus on the Counter-C indicator, as our most important index of growing skill in argumentive discourse. For purposes of examination, we also divide participants into two groups, the 21 who had shown progress from initial to final CP assessment (based on Counter-C usage) and the 7 who had not.

In Figures 1a and 1b, we present two examples of individual change patterns among the majority group of 21 who showed increase in Counter-C usage from initial to final assessment. In one case (Participant 25), the individual shows no Counter-C ability at the initial assessment but then, in collaboration with successive partners, exhibits some Counter-C usage in engaging with the three topics; at the final (CP) assessment, again working alone, she is now able to produce some Counter-C without a partner's collaboration.

Table 2
Example of Rebuttal Chain for Topic 3 (Teacher Pay)

Pair A: WE THINK THAT THEY SHOULD GET THE SAME PAY, BECAUSE SOME TEACHERS MAY LEAVE (*coded Clarify*)

Pair B: but the teachers won't leave if they think they get more pay next year + It will make them want to stick to the job (*coded Counter-c*)

Pair A: THE TEACHER'S WITH LESS EXPERIENCE WON'T THINK IT'S FAIR. BECAUSE NEXT YEAR IS A WHILE AWAY (*coded Rebuttal*)

Pair B: then they can attract experienced teachers (*coded Rebuttal*)

Another participant (Participant 10, Figure 1b) does show some Counter-C usage when working alone at the initial assessment, continues to display it to a variable degree during the intervention, and then increases this usage near the end of the intervention and in transferring back to the solo context. In both cases, then, the social collaboration experience appears to have been fruitful, and the level of performance does not revert to its original level when the social context is removed. These cases illustrate patterns most common among the groups of 21 who progressed from initial to final CP assessment.

Among the 7 participants who did not show any indication of progress from initial to final CP assessment, 4 showed equivalent performance from initial to final assessment and 3 declined slightly, with performance remaining at a low level in all cases (and 0 in one case, shown here). In all these cases, more such usage appeared during the intervention while the participant was working collaboratively, but the participant did not transfer it to the solo context of the final CP assessment. One of these cases appears in Figure 1c (Participant 28).

Within the three topics, patterns of individual performance resemble those of the three illustrative participants in Figures 1a to 1c. Variability is the norm, rather than consistent upward change, within each topic, and performance achieves its maximum levels during the first topic (as also reflected in Table 1)—an unanticipated finding we return to in the discussion of our findings. Despite this variability, there appears within the intervention sessions, at least for the 21 "progressing" participants (the group defined by progressive change across CP assessments), a common trend of progress within a topic from the beginning to final sessions of engagement with that topic. To quantify this trend, we defined a pattern as upwardly progressing over the beginning–middle–end phases of engagement with a topic if performance during the second was higher than the first and performance on the third higher than the second. We defined a pattern as mixed upward if performance at the final phase was higher than at the beginning phase, but the two intermediate links (to the middle point) reflected either plateau or decline.

Using these definitions, among the 21 progressing participants (the group defined by progressive

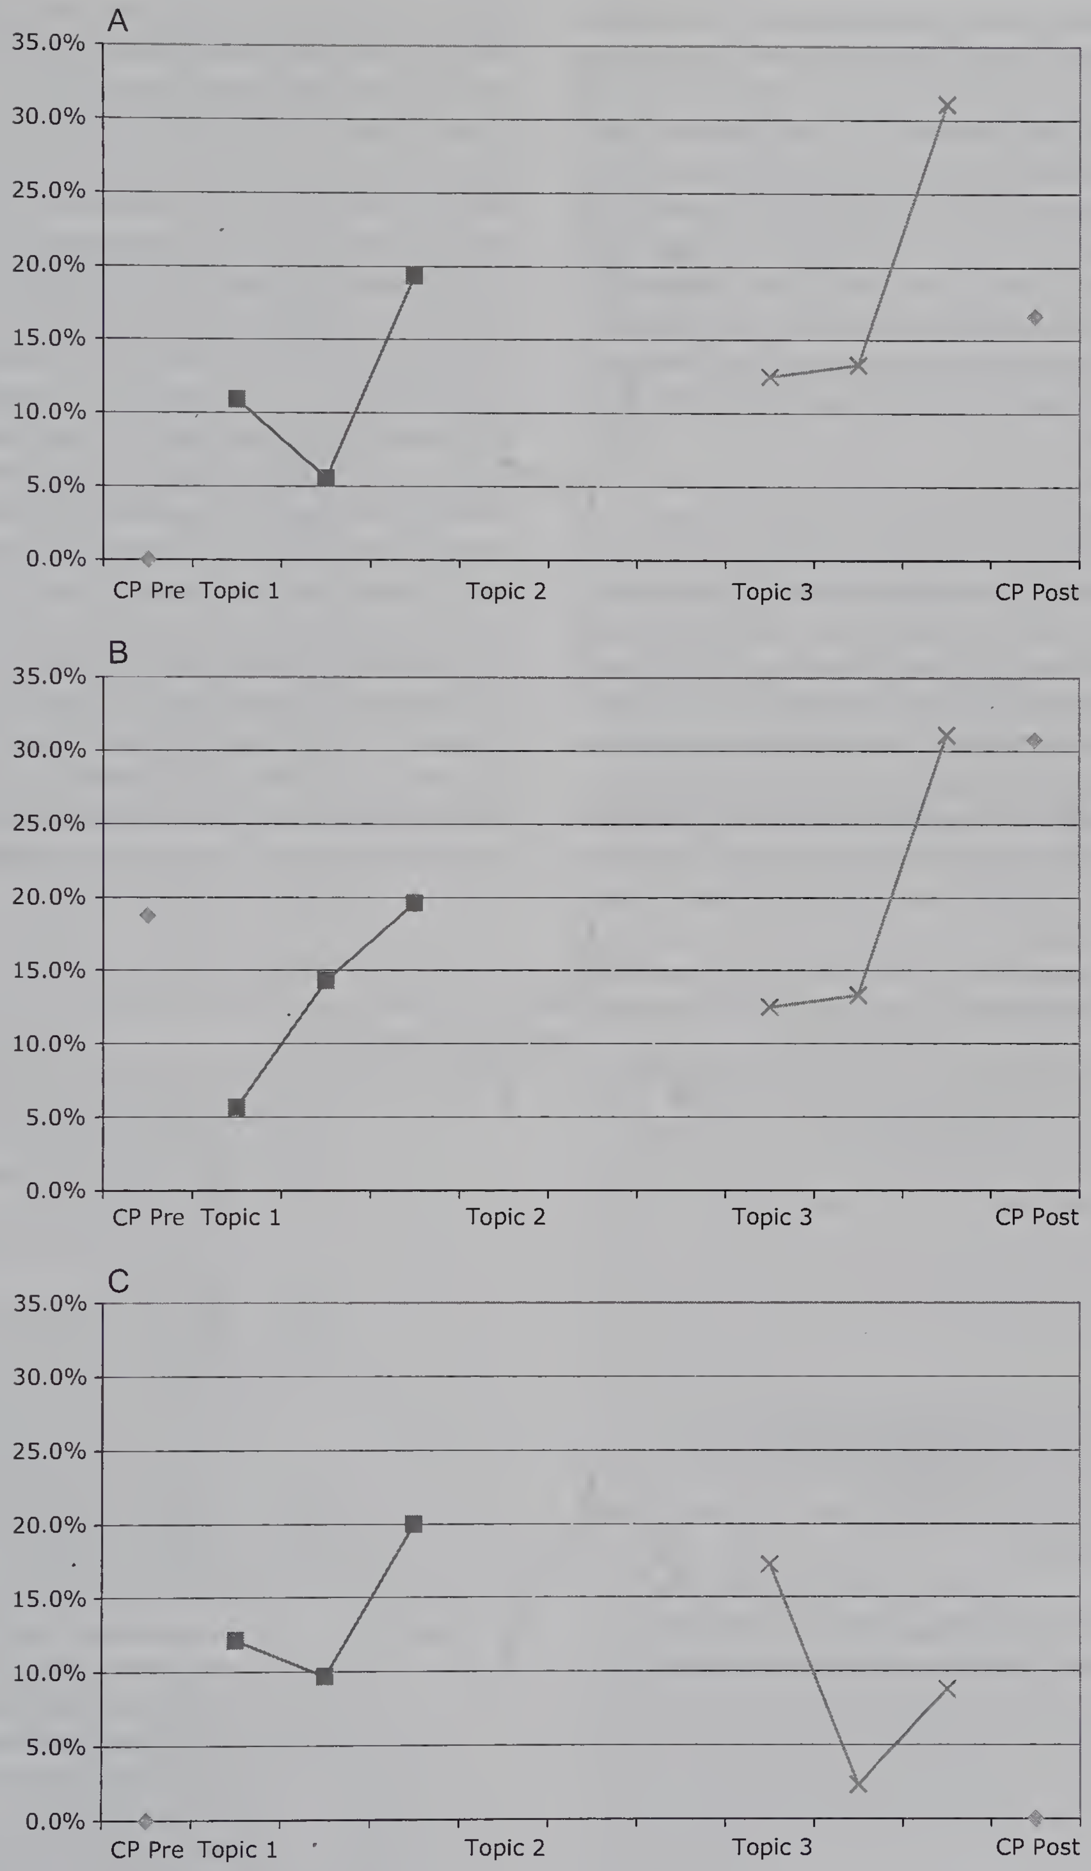

Figure 1. Percent Counter-Critique usage for discourse use across topics: (a) Participant 25, (b) Participant 10, and (c) Participant 28. CP = capital punishment.

change across the two CP assessments), the majority of patterns were in one of these two categories (upward or mixed upward)—specifically 73%. In contrast, among the remaining 7 participants who did not show progress across the two CP assessments, this percentage was 48% (roughly what would be expected if change were in no consistent direction). Although sample size is too small for meaningful statistical analysis, these findings are of interest in suggesting a link between patterns of performance during the intervention and at the initial and final (CP) assessments.

Meta-Level Development During the Intervention

Consistent with the questions we initially identified as central to the present work, our objective in this phase of the analysis was to examine the extent to which participants showed progress in recognizing the goals of argument, as distinguished from progress in implementing successful argumentive strategies. We expected progress of the former type to be most visible when participants collaborated with a partner toward a collective goal of defeating the opposing side in the showdown activity (devised to highlight this goal). We did not have resources in the present study to record the conversation between collaborating partners during the dialogs as they formulated the responses they would make to their opponents. These responses themselves, however, became a matter of record and could be examined with respect to what evidence they showed of meta-level understanding of argumentive goals and strategies. Meta-level statements we defined as statements *about* the dialog in contrast to statements that constitute the dialog. Omitted from this analysis are utterances that were meta-level but procedural in nature, for example, requesting or receiving clarification regarding task instructions or software issues and did not pertain to the dialog itself.

To further examine the nature of these meta-level statements, we developed the coding scheme shown in Table 3. The subcategories of meta-level statements appearing in Table 3 are listed in descending order with respect to their centrality to understanding of the goals and purposes of argument together with their

Table 3
Types of Meta-Level Statements

Type	Definition	Overall percent usage	Examples
Meta-directive	About the dialog, with a directive to opponent	7.59	—please state your argument —give us some reasons —give us proof and reason —Then prove it . . . —you need to give facts instead of opinion —STAte why —LETS GET BACK ON TOPIC —Please answer my question —please answer 2 our arguments!
Meta-argumentation	About the dialog, without an explicit directive to opponent	2.99	—you have not answered —u havent given good answers + so we r gonna keep askin it —that's opinion not a fact —how do you know —We're not talking about that
Meta-argument	About respective positions rather than the argumentation process	4.85	—thats our point —thats what WERE arguing for! —that is our main argument —Yeah thats what weve been trying to say —its the same argument except with some modifications —look we agree on something! —you guys agreed with us before —we never said that
Meta-comprehension	About comprehension	0.82	—You are not making sense —we don't understand —I don't get what you say man

Table 4
Mean Percent Usage for Total Meta and Meta-Directive Across Topics

	Topic 1			Topic 2			Topic 3		
	Beginning	Middle	End	Beginning	Middle	End	Beginning	Middle	End
Progressing participants									
Meta-directive	4.62 (3.90)	5.84 (5.36)	4.91 (3.64)	9.51 (6.49)	14.84 (9.59)	8.43 (7.69)	11.20 (6.28)	10.70 (9.16)	7.55 (4.77)
Total meta	15.27 (5.53)	13.39 (8.92)	11.48 (5.67)	16.64 (7.56)	25.00 (12.48)	16.84 (10.18)	25.18 (12.29)	24.21 (12.37)	21.57 (7.24)
Nonprogressing participants									
Meta-directive	6.03 (3.20)	4.82 (2.45)	6.12 (4.99)	10.15 (5.30)	6.56 (7.72)	7.43 (6.09)	10.27 (7.23)	18.09 (13.39)	9.06 (4.62)
Total meta	13.50 (5.09)	13.05 (9.37)	12.12 (9.38)	15.77 (7.17)	12.17 (5.31)	14.93 (8.53)	19.31 (8.38)	24.85 (15.72)	22.00 (10.56)

Note. Standard deviations appear in parentheses.

overall frequencies of usage. After using a portion of the data to develop the scheme, two of the authors independently coded one third of the data, achieving a percent agreement of 82% for identification and categorization of meta-level statements, with a Cohen's kappa of .69. Differences were resolved by discussion, and all remaining statements were coded by one of these two coders.

Overall change at the group level. To conduct an analysis of change over time in the various kinds of meta-level statements, as well as overall usage of meta-level statements, we again examined separately the participants in two groups, the majority group ($n = 21$) who had shown positive change in the initial to final CP assessment, and the minority group ($n = 7$) who showed no indication of such change ("progressing" and "nonprogressing" group, respectively). In Table 4, there appears for each group mean percentages of usage across time of utterances of a meta-level type. (The time intervals shown are the same as those in the earlier reported analyses in Table 1.) As seen in Table 4, for the majority (progressing) group, the mean percentage of meta-level statements increased from 15.27% at the beginning of Topic 1 to 21.57% at the end of Topic 3, a significant increase, with gains for the minority group comparable. These gains are significant for the sample as a whole, $Z = -3.552$ (Wilcoxon test), $p < .001$, effect size $r = -.671$, as well as for the progressing group examined individually. (Note, however, that in contrast to the analysis of Table 1 data, the individual, rather than the pair, must be the unit of analysis, as pair composition changes across topics. Given the lack of independence between members of a pair, significance levels should therefore be interpreted conservatively.)

Change over time was also examined for each of the subcategories in Table 3. Change is significant only for the first of the subcategories—Meta-directive. For the sample as a whole, $Z = -2.619$ (Wilcoxon test), $p = .009$, and effect size $r = -.495$ (although the same caution noted earlier applies).

These gains, however, were not maintained when participants returned to arguing against an opponent without a partner in the final (CP) assessment. Meta-level coding of the CP dialogs showed a steady rate of meta-level usage at the two points, for example, for meta-directives, 5.6% at initial and 5.8% at final CP assessment.

Individual change patterns. Examination of individual patterns of performance with respect to meta-level usage confirms that the pattern of increasing meta-level usage, in particular the Meta-directive category, is consistent across participants. Only 2 of

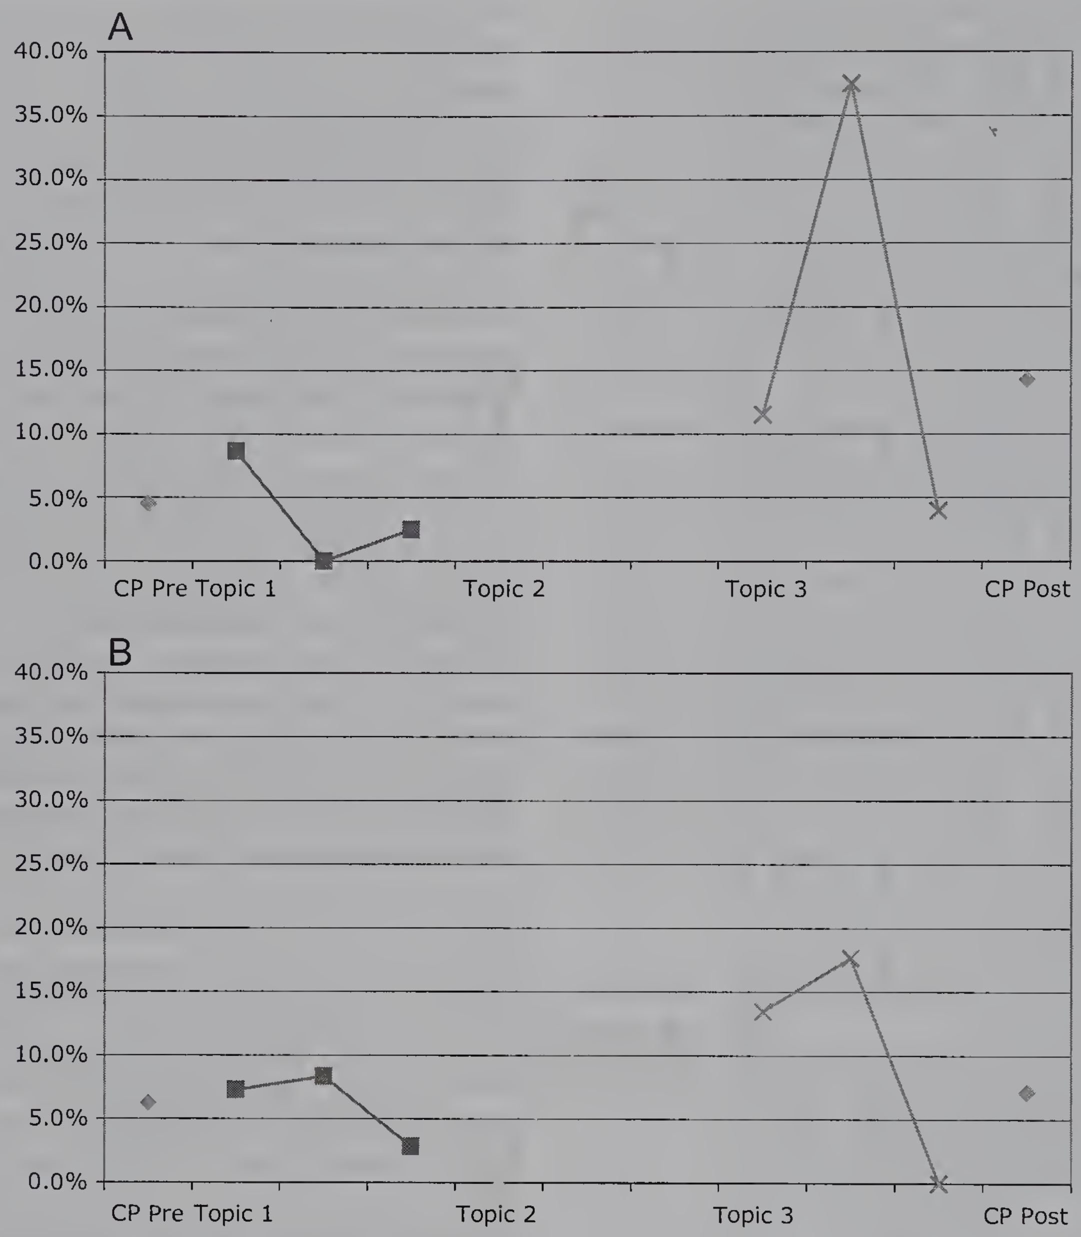

Figure 2. Percent meta-directive usage for meta-level discourse across topics: (a) Participant 19 and (b) Participant 11.

28 participants in fact fail to show such a pattern. Two typical examples appear in Figures 2a and 2b (Participant 19) and (Participant 11). As seen there, the progress reflected in Figure 2b is less dramatic than that in Figure 2a. In both cases, however, there appears the typical pattern of a decline in Meta-directive usage when the participant no longer works with a partner in the final (CP) assessment.

Implications of meta-level change. In summary, almost all participants showed increasing meta-level usage during the course of their collaborative argumentation activities. At the final dialogic assessment, no longer working collaboratively, three quarters of participants (21 of 28) showed enhanced argumentation skill (indexed by percent use of Counter-C). Did this increase in meta-level discourse about argumentation reflect understanding that contributed to the enhanced skill observed in the conduct of argumentation? Our theoretical assumptions regarding the importance of meta-level regulation of behavior suggest a positive answer, but it is not straightforward to identify strict causal evidence of such an effect. Because meta-level discourse emerged and increased over time in almost all participants, we cannot compare those who did and did not engage in meta-level discourse. Furthermore, participants worked in pairs during the intervention, and we cannot be sure that the meta-level discourse directed to the opponents was contributed to equally (or at all) by each member of the pair (and would therefore be expected to affect the individual skill assessment of both members of the pair).

In search of some further evidence of the contributory role of meta-level processes, we examined pairs who showed more versus less than the typical proportion of meta-level discourse to assess whether these two groups would differ in argumentation skill level. For this analysis, we chose Topic 2, when meta-level discourse was most likely to have emerged, after participants had become familiar enough with the activity to begin to reflect on how best to carry it out. We divided the Topic 2 pairs (partners differed, recall, for the other two topics) into those who showed relatively high proportions of statements in the meta-directive category (15% or more) and those who showed lower proportion of statements in the meta-directive category (less than 15%). Of the 14 pairs, 8 fell into the high category and 6 into the low category. For each pair, we calculated the mean of the 2 pair members' proportion usage of Counter-C at the final (CP) dialogic assessment. Among the 8 high meta-directive pairs, 7 showed Counter-C usage equal to or greater than 15%. Among the 6 low meta-directive pairs, only 1 pair showed Counter-C usage equal to or greater than 15%—a significant difference (Fisher exact test, $p = .026$). Although this comparison involves small numbers and should only be regarded as suggestive, it does offer some evidence of a link between meta-level discourse and argumentation skill.

Showdown

Although we did not formally analyze performance in the showdown preparation sessions, we did undertake the same discourse analysis of the three showdown transcripts as was performed on the intervention dialogs. Here, we saw that the focused group effort produced a higher level of skill than that observed during the dialogs between pairs. The overall percentages of showdown Counter-C statements were 58% for Topic 1, 61% for Topic 2, and 70% for Topic 3. To illustrate the level of performance that participants achieved as a group, we present in the Appendix the (slightly edited) showdown debate produced for the homeschool topic in the form of the argument map presented to students at the session following the showdown for this topic. The Appendix contains a black and white version (with effective moves in bold and ineffective in dotted lines) rather than the colored version (with green and red boxes) that students saw.

Discussion

Our findings highlight the value of the microgenetic method in providing a clearer and fuller picture of the changes that occurred among our participants than would have been evident from the pretest–posttest assessments alone. We therefore discuss our results in the reverse order in which they were presented, beginning with the microgenetic data on meta-level change and then proceeding to change at the strategic level and finally to the pre- and posttest assessments of first dialogic and then individual argument skills.

On virtually all the dimensions we examined, some participants were identified who failed to show progress. This group was smallest in number, however, on the dimension of meta-level discourse. Of the 28 participants, 26 showed a pattern that involved increasing usage of meta-level discourse, in particular meta-directives to the opposing pair. As elaborated earlier, we see this meta-level discourse as significant in indicating at least implicit understanding of the functions and objectives of argument. When participants say to their interlocutors, "Give us some reasons" or "You have not answered," they are displaying implicit understanding of what contributors to a dialog need to do in order to engage effectively in argumentation.

It is notable that these increases on the part of almost all participants were evident only when participants were engaging in the dialogic task with a collaborating partner. When participants again worked without a partner (at the final CP dialogic assessment), these increases were no longer evident (as reflected in comparisons of initial and final CP dialogs). In the collaborative context, participants had the cognitive and social support of one another in formulating their contributions to the dialog and indeed needed to collaborate in order to perform their task. They also shared the social goal of prevailing over the opposing side in the showdown. Neither of these conditions existed when they argued individually with an opponent on a different topic, one that they had discussed only once before and without a particular objective. We cannot say with certainty whether under the latter conditions participants lost sight of argumentation objectives that they were aware of in the collaborative condition. We see as a more likely interpretation, however, that they simply perceived no need to express them in meta-level talk in the solitary condition. They had a task to do (to debate the CP topic with an opponent), and there was no one they needed to consult with as to how best to carry out the task, so they simply got on and applied their skills to the task, with little comment on their own or their opponent's performance. If so, our findings point to the importance of social context and goal structure in influencing performance—a conclusion also reached by Nussbaum (2005) in a study of argumentation in a college-student population. The association we observed between extent of meta-directive discourse and later individual argument skill nonetheless supports the view that this meta-level discourse was productive with respect to skill development.

Turning to the strategic skills themselves, it is notable that, in contrast to what was the case for the meta-level discourse just discussed, positive change over time did not diminish when participants return to the nonsocial context of working without a collaborating partner and without a social goal. Counterargument and rebuttal, which lie at the heart of argumentation, increased in frequency among three quarters of the participants from initial to final CP assessment, and all participants showed some skilled counterargument (Counter-C) at the final assessment (compared to only a third at the initial assessment). The increase in frequency of skilled counterargument (Counter-C), to 21.37% of discourse, is consistent with our earlier studies involving similar methods (Felton, 2004; Kuhn & Udell, 2003; Udell, 2007), and the amenability of argumentation skill to increased usage with exercise and scaffolding of various kinds is also consistent with other lines of research involving both children (Anderson et al., 2001; Nussbaum, 2003; Reznitskaya et al., 2001) and young adults (Clark & Sampson, 2005; Glassner & Schwarz, 2005; Nussbaum, 2005).

An unexpected finding, revealed by microgenetic analysis, is that strategic-level (although not meta-level) gains were concentrated in the first third of the intervention activity (Table 1). We cannot, of course, be certain that the gains documented at the final (CP) assessment would have been the same had the participants not had the further experience of engaging in the second and third phases of the intervention. Still, we are left with the question of why they did not show further strategic gain during the second and third phases.

Although numerous explanations are plausible (e.g., motivational factors or ceiling effects), the explanation we favor derives from our going back to the dialog transcripts and comparing their content across the three intervention topics. Although we did not intend it, there may have been a subtle difference across topics. The first topic, the homeschool topic, was characterized by well-defined opposing positions (the protagonist in the dilemma is either homeschooled by his parents or attends the townschool), either of which could plausibly lead to a satisfactory outcome. The second topic, school expulsion, also had well-defined opposing positions (the misbehaving students are removed from the school or are not). In this case, however, neither alternative can be expected to lead to a satisfactory outcome for the misbehaving students. In the words of a number of our participants on both sides of the issue, "That won't solve the problem." Participants on one side noted that these students would continue to disrupt if not removed, whereas participants on the other side often noted that the students would just cause the same disruption if removed and sent elsewhere to school. The latter group thus devoted considerable dialog to proposing other solutions (e.g., bringing in a social worker or counselor to work with the misbehaving students) that would resolve the problem.

What we may be seeing here, we believe, however, is a shift in goal structure, driven by the topic content, from the classic *argument* goal structure (having one's position prevail over that of an opponent) to the *dilemma resolution* goal structure of resolving the underlying problem that the two opposing sides address. Our dialogic coding scheme, which classifies the function, not the content, of utterances does not provide direct evidence of such a shift across topics, and it must remain speculative. Our discourse analysis of the three showdowns, however, showed that even if participants were diverted from counterargument/rebuttal in their paired dialogs during the later topics, their skill in counterargument was not compromised when they proceeded to the focused context of the showdowns.

The appearance of a shift in focus during the paired dialogs becomes even more pronounced in examining dialogs on the third topic, teacher pay. A subgroup of participants on the experience-based-pay side of the issue during the course of the dialogs identified as their position a third alternative, merit-based-pay, acknowledging weaknesses of the original experience-based-pay position. Some of their dialog was thus diverted to identifying and elaborating this new position and away from counterargument against the opponents' position.

Should we regard such shifts as advances, as refusals to accept the opposing positions as defined and the seeking of a "third way?" Such an interpretation is consistent with the ideas of philosophers such as Gilbert (1997), who defines a model of what he calls "coalescent argumentation," the goal of which is to enrich group understanding rather than pit sides against one another—the sort of model that has been proposed by some psychologists as a possibly more fruitful model for instructional interventions (Anderson et al., 2001; Nussbaum, 2005).

While appreciating Gilbert's model, as developmentalists, we are inclined to see the value of older children and adolescents gaining mastery of traditional argumentation structure, as a foundation for acquiring skill in more complex argument forms. In previous research (Kuhn & Udell, 2007), we have observed young adolescents rely on what we called an avoidant pattern in addressing very simple arguments, stating, for example, "I'd just play both," in response to a question about the merits of choosing soccer versus basketball as one's sport. Mastery of the traditional argument – counterargument – rebuttal structure involved in debating two opposing positions, in our view, is a component of, and hence a necessary foundation for, engaging in more sophisticated forms of "coalescent" argumentation. In its absence, inexperienced arguers may find themselves uncertain as to whether a potential contribution to discourse that they may be contemplating is simply an unanchored addition to the current talk about the topic ("Here's another thing that might be relevant") or has an identifiable function to perform in the discourse.

We note, finally, that advances in dialogic argumentation skill did show evidence of influence on the individual written arguments collected as part of the final assessment. Although demonstrating such effects was not the focus of the present work, it is of course a result one would hope for, as well as one that has been reported in previous studies of the effects of discourse on individual argument skills and/or conceptual understanding in both children younger than those in the present study (Anderson et al., 2001) and in adults (Nussbaum, 2005), as well as in our own earlier work with the age group studied here (Kuhn et al., 1997). Note that new, more adequate reasons in support of his or her position on CP are not ones a participant would have had an opportunity to be exposed to from an external source. The most likely interpretation of their appearance, in our view, is that it is the cognitive effort of considering multiple views and generating counterarguments and rebuttals with respect to them, as well as the benefit noted earlier of increased awareness of the "missing interlocutor," that is responsible for the shifts observed toward more adequate, higher level reasons to justify one's position and away from less adequate, lower level ones.

Because our major interest in the present work was on the development of dialogic argument skill, we included as the main focus of our initial and final assessments the dialogic argument skill that a participant displayed in the absence of the social support that characterized the intervention. As a result, participants had some, albeit very limited, dialogic experience with the transfer (CP) topic, and this experience could have contributed to the improvements observed in their ability to produce an individual argument in support of their position on the topic. Evidence against such an effect, however, comes from a study by Udell (2007), with the CP topic among a slightly older adolescent group, in which no improvements occurred in either dialogic or individual skills as the result of simply an initial assessment of these same skills several months earlier. In future work, a fuller assessment of individual argument skills, and how they are affected by advances in dialogic and meta-level argumentation skills, is warranted to further elucidate the suggestive gains observed in this study.

In conclusion, the microgenetic method employed here has shown that argumentation skills are amenable to development with engagement and practice in a scaffolded context yet without direct instruction. In light of the earlier noted weaknesses in argument skills reported by educators among students at the high school and even college level, this finding alone is notable, especially given that our results also support the idea of dialogic argument as a developmental pathway to individual argument skills of the sort emphasized in academic contexts.

In addition, however, the present work we believe points to the importance of meta-level awareness and understanding of argumentation rather than simply the implementation of argument strategies at the performance level. Understanding and appreciating the value of argument is an epistemological achievement (Kuhn & Park, 2005). In the broad sense, this means seeing the point of argument and coming to appreciate it as the ultimately most powerful means of influencing others' thinking. Only in so doing will one be disposed to invest significant effort in developing the skills that argument entails. Children need to learn that argument is more than something to be avoided. This understanding is not intuitively given. Certain cultural values (to "live and let live" and to show tolerance toward others' views and avoid risk of offending) work against it, and only a more advanced level of epistemological understanding supports it (Hofer & Pintrich, 1997, 2002; Kuhn, 2005; Moshman, 2005).

In the narrower sense, this meta-level understanding entails understanding of the objectives of argument and specifically of the relevance of the other person's position. If the opponent's position is not relevant, the process through which one achieves victory over the opponent cannot be regarded as one of argument. Kuhn and Udell's (2007) study of children's and adults' arguments found, in both groups (although to a greater extent among children) and in multiple (open- and closed-ended) formats, a preference for articulating one's own position over examining and addressing the other's position. As noted earlier, this finding supports the view that the developmental challenge may lie more in understanding the relevance of argument strategy than in executing it. If so, the present work suggests that such understanding is amenable to development.

Leitao (2003) showed college students a series of short essays together with additional sentences of counterargument and rebuttal to the main argument, which could potentially be inserted into the essay.

Students were divided in their opinions as to whether adding such counterarguments and rebuttals would improve the persuasiveness of an essay. Such findings highlight the importance of meta-level development with respect to argumentation. Although tracking this meta-level development is less straightforward than tracking development at the strategic level of performance, both seem essential.

The Influence of Race and Gender on Children's Conversations and Playmate Choices

Patrick J. Leman
Royal Holloway, University of London

Virginia L. Lam
University of East London

The present study examined the influence of race and gender on children's conversations and friendship choices. Four hundred and twenty-eight children (*M* age = 7.5 years, *SD* = 0.34) from 2 racial minority groups (i.e., African Caribbean and South Asian) and the racial majority group (i.e., European) chose a picture of a playmate together with a peer. Race influenced the levels of assertion and affiliation in children's conversations. The effects of race on conversation also varied according to the gender of the children involved in interaction. Same-race pairs tended to choose in-group playmates, but same-race minority pairs showed less marked in-group preference. Cross-race pairs selected a majority-group child as a playmate most often.

The present study investigated, for the first time, how race influences the social dynamics of conversations between children when they choose a playmate together. Previous research has established an association between race and friendship from preschool onward. A consistent finding is that there is racial cleavage in playmate choices; that is, children tend to play with peers from the same-race group more frequently than with peers from other-race groups (Finkelstein & Haskins, 1983; Fishbein & Imai, 1993). Although these in-group racial biases can be identified in the attitudes, judgments, and behavior that children exhibit, a key context in which these biases become visible is in interaction and conversation. Although conversations with adults may not be free from the influence of race, peer conversation is where most children will establish their friendships and learn about relationships with others for themselves. By focusing on the influence of race on conversations and playmate choices between peers, the present study provides a fresh perspective on questions of children's racial and intergroup understanding and on how aspects of children's identity may influence their conversations. Moreover, this research contributes to a better understanding of the links between race and other related processes including friendship (Aboud, Mendelson, & Purdy, 2003; Lease & Blake, 2005), peer relationships (Killen & Stangor, 2001; Wright & Tropp, 2005), and the reduction of prejudice through intergroup contact (Aboud & Fenwick, 1999; Doyle & Aboud, 1995; Kenworthy, Turner, Hewstone, & Voci, 2005). Three questions guided the present study: First, does race influence the social dynamics of children's conversations about who to choose as a playmate? Second, does race influence the joint choices of playmates by children? Third, what are the relations between children's conversations and their choices of playmates?

The focus on the specifics of children's exchanges offers an opportunity to examine how contact can be productive or destructive in terms of broader relationships between children. Interpersonal contact is often proposed as a mechanism for reducing prejudice and creating good race relations (Cameron, Rutland, Brown, & Douch, 2006). However, if this contact creates or maintains negative forms of interaction, or reinforces stereotypes, its value is questionable. Alongside informing debates about interracial contact between children, the present study also addresses a gap in research on children's conversations because previous studies in this area have focused either on racially homogenous samples or have not directly examined the impact of race on conversations (Leaper & Smith, 2004; Quintana et al., 2006).

It is, perhaps, surprising that no previous work has sought to unravel the ways in which a child's race can affect their conversation style. In contrast, a good deal of research has charted how gender influences

---

The research reported here was supported by a grant from the Nuffield Foundation (SGS/00735/G). We would like to thank all the schools, teachers, and children who participated in this research. We would also like to thank Martyn Barrett, Margaret Harris, Carol Levine, Katy Marcus, Ned Palmer, Kathy Rastle, Harriet Tenenbaum, Dawn Watling, Donald Wells, and five reviewers for feedback on earlier drafts of this article.

Correspondence concerning this article should be addressed to Patrick J. Leman, Department of Psychology, Royal Holloway, University of London, Egham, Surrey TW20 0EX, United Kingdom. Electronic mail may be sent to Patrick.Leman@rhul.ac.uk.

children's conversations. Gender differences in conversation have been attributed to different socialization experiences that result in separate male and female (or two cultures of) conversation styles (Maltz & Borker, 1982). As with gender, from early childhood, children realize there are different races (Aboud, 1988), and by the end of middle childhood, children associate different racial groups with specific stereotypes and make predictions about behavior and preferences that are based on race (Lam & Leman, 2003; Powlishta, Serbin, Doyle, & White, 1994). In this respect, children develop a sense of their own and others' identities as a result of their membership in different social groups (Tajfel & Turner, 1986). Membership in these groups entails different socialization experiences that may feed into race differences in conversational style and dynamics. Much like the two cultures approach to gender and conversation style, there may be different cultures of conversation style associated with race.

Gender differences in conversation have also been attributed to status differences or status characteristics that stem from perceived social asymmetries in gender relations (James & Drakich, 1993). In this respect, cross-gender interaction (i.e., between a boy and a girl) involves an asymmetric status relation between children because the contact is with a member of the gender out-group. However, interaction exclusively between children of the same gender involves contact with another in-group member and, as a consequence, may be more symmetric. These in-group and out-group dynamics are associated with differences in status that, it is argued, lead to differences in conversational dynamics between boys and girls in same- and cross-gender interaction. Race, like gender, marks out social groups that are associated with different status characteristics. Given that gender is a dominant force in shaping children's conversation styles, other aspects of a child's social identity such as race may influence conversation styles too.

The first set of hypotheses addressed whether race influences children's conversation dynamics. Our first hypothesis directly examined whether there would be differences in conversational style between race groups. Specifically, we predicted that there would be differences in children's levels of assertion and affiliation depending on a speaker's racial group (i.e., African Caribbean, European, and South Asian). Assertion and affiliation are identifiable and recognizable features of children's conversations (Leaper, 2000) that offer a systematic means for gauging the dimensions of conflict, cooperation, and dominance in children's interactions. As such, they are markers of the social dynamics of children's conversations and have been linked to gendered styles of speech and to differences in status between children. Although we predicted that race would affect children's conversation styles, in the absence of previous research, we made no predictions about how the levels of assertion and affiliation relate to particular race groups.

We also anticipated that children would respond to the race of their conversation partner and the racial mix of a pair because, like gender, race is a social category associated with differences in status between groups. European (i.e., majority group) children and adults are often perceived to hold higher status in society (Brown & Bigler, 2005). Therefore, our second hypothesis examined whether status characteristics would affect the level of assertion and affiliation displayed by children. We predicted that in cross-race pairs, European children would be more assertive than their African Caribbean and South Asian conversation partners. Our third hypothesis was derived from work on intergroup dynamics indicating that individuals tend to affiliate more with in-group members and disaffiliate (or, at least, do not affiliate as strongly) with out-group members. We therefore predicted that children in same-race pairs would display higher levels of affiliation than children in cross-race pairs.

Our primary focus was on race and conversation, but a corollary issue is whether gender and race interact to affect children's conversations in different ways. No previous work has explored directly the connection among race, gender, and conversation. Some work has suggested that some elements of the influence of gender on conversation may cut across racial groups. Leaper, Tenenbaum, and Shaffer (1999) examined the conversations of African American children using a puppet-play task. The results from that study broadly replicated those from an earlier study (Leaper, 1991) of mostly European American children that examined whether or not gender influenced children's conversations. Both studies found that conversations between boys were more domineering, whereas conversations between girls were generally more collaborative. Results also showed that boys and girls were less controlling and domineering when in conversation with a girl than when in conversation with a boy. Indeed, a meta-analysis of studies of gender and conversation revealed that, on average, girls are more likely to use language to connect or affiliate with others, whereas boys are more likely to use language to dominate or assert themselves over a conversation partner (Leaper & Smith, 2004). Subsequent to our analysis of race, in the present study, we analyzed boys' and girls' pairs separately to explore whether these effects of gender in conversation interact with those of race.

The second set of hypotheses addressed whether race influences children's choice of a playmate. Racial cleavage in play is evident from preschool (Fishbein & Imai, 1993; Hallinan & Teixeira, 1987a; Howes & Wu, 1990), but the divisions between children from different racial groups are even more apparent among older children (Boulton & Smith, 1992). More recent research has indicated that the number of cross-race friendships declines with age and that such friendships are less stable and intimate than same-race friendships. European American children are less likely than minority-group children to choose a peer from another racial group as a friend (Aboud et al., 2003), but the racial mix of a school affects the level of minority-group bias and friendship choices among European American children (McGlothlin & Killen, 2006; McGlothlin, Killen, & Edmonds, 2005). Additionally, majority and minority children who have friends from ethnic minority groups in a school differ from one another on a number of social, behavioral, and affective measures (Lease & Blake, 2005). Therefore, although evidence suggests that race affects children's friendship choices, the association between race and friendship is complex and can be influenced by context. By exploring playmate choices in a conversational context, the present study provides a fresh perspective on how race influences children's social relationships.

Our fourth hypothesis reflects the broad finding that children tend to choose playmates from their own race. We predicted that same-race pairs would choose playmates reflecting an in-group preference. The fifth hypothesis predicted that in pairs from different race groups (i.e., cross-race pairs), there would be less agreement about the choice of a preferred playmate. This prediction is consistent with previous research with adults (Garcia-Marques & Mackie, 2001), which has found that individuals are more easily persuaded by an in-group than an out-group member.

The third set of hypotheses concerns the links among race, conversation, and children's choices of a playmate. Contact between individuals of different groups can reduce prejudice toward out-groups in general (e.g., Pettigrew, 1997; Pettigrew & Tropp, 2006) and in minority groups in particular (Tropp & Pettigrew, 2005), although the type of contact is crucial in determining its effectiveness in reducing prejudice (Kenworthy et al., 2005). Conversation is a key element in any contact. Aboud and Levy (2000) found that conversations between peers reduced racial prejudice and promoted positive racial attitudes in children. Aboud and Doyle (1996) found that children who talked with a less prejudiced peer experienced a reduced level of prejudice (see also Aboud & Fenwick, 1999).

If race affects children's conversation style, then it is also likely that race will affect the outcomes or decisions that are made. Leman, Ahmed, and Ozarow (2005) found that levels of assertion and affiliation correlated with different outcomes in children's conversations. For example, compared to conversations where one child won, when children reached a compromise, conversations tended to be more balanced, both in terms of each partner's contribution to the discussion and their levels of assertion and affiliation. Consequently, our sixth hypothesis predicted that unresolved conversations (i.e., where there is no agreement about a playmate) would involve high levels of assertion and low levels of affiliation.

The seventh and eighth hypotheses stem from an assumption that race and conversation dynamics would link with the decisions children reached about a playmate. Our seventh hypothesis predicted that when children in same-race pairs agree on a playmate from their racial in-group, they will exhibit high levels of affiliation. In contrast, for our eighth hypothesis, we predicted that when children in these pairs choose a playmate from their racial out-group, they will exhibit low levels of affiliation. Although we anticipated fewer resolved conversations in cross-race pairs, we made no predictions about the links between conversation measures and choices of playmate when cross-race pairs agreed.

The focus on children between 7 and 8 years of age identifies a particularly important age group for the study of racial understanding. Although children hold negative racial attitudes toward out-groups during early childhood, these attitudes start to become more positive from around 7 years, at least in terms of their explicit expression. This increasing positivity in attitudes, however, coincides with a decline in the selection of children from other racial groups as friends (Hallinan & Teixeira, 1987a, 1987b). Perhaps from this age peer influence becomes a more powerful force in children's decision making and contributes to in-group (i.e., same-race) friendship choices. Therefore, although at this age children's attitudes may be becoming more positive toward minority groups, increasing peer (i.e., in-group) influence may limit the number of cross-race friends (Abrams, Rutland, Cameron, & Marques, 2003). These changes may, in turn, be linked to more general developmental changes in underlying cognitive processes (see Powlishta et al., 1994). Participating children were members of the predominant racial groups in London, which constitute the majority group and the two largest racial minority groups in both the city and the country as a whole. This choice of racial groups made sense not only because it allowed a maximum number of interactions to be observed but also because such interactions between children would be most frequent in this multiethnic context.

Method

Participants

Four hundred and twenty-eight children (*M* age = 7.5 years, *SD* = 0.34, 210 boys and 218 girls) participated in the present study. Children were recruited from eight schools from the same working class (i.e., low-socioeconomic-status) area of London, United Kingdom. All the schools were in close proximity to one another and shared a similar racial composition. There were 103 children of South Asian racial origin who include those with familial racial origins in India, Pakistan, and Bangladesh. There were 99 children of African and Caribbean racial origin. Finally, there were 226 children of European racial origin. Mixed-race children and those from other ethnic groups participated in paired discussions, but because the numbers in each group were small, these data are not included in the analysis.

Schools keep no record of pupils' race, but the most recent data (United Kingdom Government, Office for National Statistics, 2005) for the racial composition of residents in this part of London indicated that 64% of the population was European, 11.2% was South Asian, and 20.4% was African Caribbean. Nationally, 92.1% of the population is European (i.e., the largest racial group), 4% is South Asian (i.e., the second largest group), and 2% is African Caribbean (i.e., the third largest group). However, teachers estimated that between 65% and 75% of the students came from ethnic minority groups, which is plausible given the high birth rates among ethnic minority groups. In other words, although African Caribbean and South Asian children constitute a racial minority across the United Kingdom, there was no clear racial majority group in the schools that participated in this study.

To facilitate analysis, pairs were divided into two separate samples: the first sample (*N* = 220) compared South Asian and European children and the second sample (*N* = 208) compared African Caribbean and European children. The two samples produced two separate sets of all-European pairs. A comparison of these two sets enabled a cross-check for equivalence of these all-European pairs from the two samples.

Procedure

Eight photographs, each showing a target child who was in the same age group as the participants, were presented to the pairs. For the European and South Asian sample, four of the eight target children were European (i.e., two boys and two girls) and four of the eight target children were South Asian (i.e., two boys and two girls). For the European and African Caribbean sample, four of the eight target children were European (using the same photos shown to the European and South Asian sample) and four of the eight target children were African Caribbean (i.e., two boys and two girls). The eight target children's ages, attractiveness, and racial typicality were matched by adult and child judges in testing before the interaction phase of the study.

Children were placed in a pair with a peer of the same sex. There were five different pairings for boys and girls: (a) all African Caribbean (henceforth AC–AC), (b) all South Asian (henceforth SA–SA), (c) all European (henceforth Eu–Eu), (d) African and European (henceforth AC–Eu), and (e) Asian and European (henceforth SA–Eu). Because of insufficient numbers of racial minority-group children, it was not possible to create African and Asian pairings. Only same-sex pairs were used in this study because including boy–girl pairs would have added greatly to the complexity of the design. Children were paired to ensure an equal number of different pair types. Dyad composition was also determined after discussing the children's verbal ability, intelligence, and sociometric status with the class teacher. The latter matching variable meant that the dyadic partners were seen to be reasonably agreeable classmates who were not best friends. Pairs were not explicitly matched for socioeconomic status, but given the area in which the schools were located, the overwhelming majority of children were from low-socioeconomic backgrounds.

Each pair of children was interviewed in a quiet room by a female interviewer who said, "I am interested in how children choose other children to play with." The photographs of the potential playmates were laid out in random order in front of the pair, and each pair was asked, "Imagine that these children were going to be new children in your class. Now, if you had to pick just one of them you both would most want to play with, which would that be? Do think about it together before picking." Each dyad was permitted 3 min to reach their decision. Pairs were able to choose one photograph from the eight. In the event that the children did not reach a consensus at the end of 2 min, the children were told they had 1 more minute to decide. The interviewer's input was kept to a minimum unless the children initiated interaction (e.g., asking questions) or were silent. If the children were silent, the interviewer attempted to encourage the children to interact. A video camera was used to film the interaction between the dyadic partners.

There were five possible outcomes in the European and South Asian sample: European boy, European girl, South Asian boy, South Asian girl, and no decision (unresolved). There were also five possible outcomes for the European and African sample: European boy, European girl, African boy, African girl, and no decision (unresolved).

Given there were multiple racial pairings, it would have been impractical to counterbalance interviewer race and gender across all pairings. The interviewer's racial origin, however, was East Asian (i.e., Chinese), which constituted an out-group for all the children in this study. Therefore, many of the potential pitfalls of having an interviewer from the majority group were avoided. In addition, using a single interviewer ensured consistency of practice across pairings.

Measures of Conversational Style

The Psychosocial Processes Ratings Scale (PPRS; for more details, see Leaper, 2000) was used in the present study to explore children's use of assertion and affiliation. PPRS has two separate, independent 7-point scales for rating levels of personal assertion and interpersonal affiliation. These scales provide detailed descriptions about specific, common behaviors, such as asking for another's opinion (Level 6 affiliation, moderately interdependent) or agreeing with another's position without comment (Level 2 assertion, moderately nondirect). The first author (of European ethnic origin) of this article made separate ratings for each child every 5 s. Therefore, there are ratings every 5 s for a child's behavior, and these ratings range from unassertive (i.e., nondirective behavior such as sitting passively and withdrawing from conversation) to highly assertive behavior (i.e., giving commands or demands, strong disagreement, and aggression). Similarly, there were ratings every 5 s for levels of affiliation, and these ratings ranged from unaffiliative (i.e., highly distant behavior, such as active resistance, outright rejection, or strong disagreement) to highly interdependent behavior (i.e., joining in or clear cooperative activity). Average assertion and affiliation scores were calculated for each child. High scores on each of the separate scales indicated high assertion and high affiliation.

Reliability of Conversation Measures

To test the reliability of the PPRS scores, a second judge (i.e., the second author, who is of Chinese ethnic origin) blind coded 20% (i.e., 42) of the conversations that were selected at random. Agreement on coding for PPRS categories was good: assertion, $\kappa = .84$; affiliation, $\kappa = .72$.

Results

Design and Analysis

A between-subjects design was used to analyze each sample. The child's race (i.e., African Caribbean, European, and South Asian) was a blocking variable, and the predictor variable was the racial mix of the pairing. For the South Asian and European sample, the racial mix was either two South Asian children (SA–SA, $N = 35$), two European children (Eu–Eu, $N = 42$), or one South Asian child and one European child (SA–Eu, $N = 33$). For the African Caribbean and European sample, the racial mix was either two African Caribbean children (AC–AC, $N = 32$), two European children (Eu–Eu, $N = 37$), or one African Caribbean child and one European child (AC–Eu, $N = 35$).

There were three dependent variables and measures. Two dependent variables related to conversation measures that concerned how the racial mix of the pair and the race of the speaker and partner influenced children's use of communication styles (i.e., assertion and affiliation). Analyses of children's levels of assertion and affiliation were based on scores that ranged from 1 to 7. The joint decisions that children in different pairs reached about which playmate they would pick related to the third dependent variable. All the children chose a same-gender playmate; therefore, this outcome choice of preferred playmate was classified only in terms of race (i.e., African Caribbean, European, and South Asian).

The results reported here focus on three separate units of analysis: (a) the pair, (b) the individual child, and (c) the child's conversation partner. The analysis of dyadic interaction presents a particular statistical challenge to researchers. Specifically, the contribution to a conversation of one dyad member is (almost inevitably) dependent on the contribution of their partner (Gonzalez & Griffin, 2000). Correcting for nonindependence allows an assessment of the impact of a speaker's and a partner's race on a conversation. It also allows a comparison of the extent of race differences between same-race and cross-race pairs.

In the present study, we adapted a technique developed by Carli (1989a, 1989b) and Kraemer and Jacklin (1979) for use in analyzing gender effects in conversation but replaced the binary distinction between gender groups with a binary distinction between different racial groups in each sample. This technique involves applying a set of formulas to the means and mean error terms in two separate analyses of variance (ANOVAs). In this study, a first ANOVA with race as a between-groups factor was carried out for the same-race pairs, and a second ANOVA with race as a within-groups factor was carried out for the cross-race pairs.

The formulas for each comparison share a common denominator: $([2M_{se} + 2MS_e'][1/n])^{1/2}$, where M_{se} equals mean error score for race effects in same-race pairs (in each separate group), MS_e' equals mean error score for race effects in cross-race pairs (in each separate sample), and n equals the number of observations used in the analysis. Using the South Asian–European group as an example, the numerators for each effect (i.e., speaker, partner, and interaction) were as follows: speaker race effects ($[M_{\text{as}} + M_{\text{am}}] - [M_{\text{ws}} - M_{\text{wm}}]$), partner race effects ($[M_{\text{as}} - M_{\text{am}}] + [M_{\text{wm}} - M_{\text{ws}}]$), and interaction effect ($[M_{\text{as}} - M_{\text{am}}] - [M_{\text{wm}} + M_{\text{ws}}]$), where M_{as} equals mean for Asian in same-race pairs (SA–SA), M_{am} equals mean for South Asian in cross-race pairs (SA–Eu), M_{ws} equals mean for European in same-race pairs (Eu–Eu), and M_{wm} equals mean for European in cross-race pairs (SA–Eu).

These formulas transform the ANOVA output scores and provide separate values of the t statistic for tests that relate to race in each of the separate parameters (i.e., speaker and partner race effects and interaction effects). For speaker and partner race effects, a positive value of t indicated a larger score for South Asian or African Caribbean children compared to European children. For the interaction effect, a positive value of t indicated that the difference in the use of conversation measures is greater in same-race pairs than in cross-race pairs.

Race and Conversation Style

The first set of hypotheses concerned the links between race and conversation. Our first hypothesis predicted differences in levels of assertion and affiliation that were linked to a speaker's race. Our second hypothesis predicted that European children would be more assertive than their African Caribbean and South Asian conversation partners in cross-race pairs. Our third hypothesis predicted that children in same-race pairs would display higher levels of affiliation than children in cross-race pairs. The results relating to these three hypotheses are organized in terms of effects of speaker race, effects of partner race, and the interaction effect. The analyses are presented first for all children in a sample, then separately for boys and girls in the sample.

Variations in the use of assertion and affiliation were examined for both samples. Speaker, partner, and interaction effects for the South Asian and European sample are presented in Table 1. Corresponding mean scores and standard deviations are broken down by race and pair type (same- and cross-race pairs) in Table 2. Additionally, results from the between-group (comparing between South Asian and European children in same-race pairs) and within-group (comparing South Asian and European children in the cross-race pairs) ANOVAs are given in Table 2. Table 3 reports speaker, partner, and interaction effects for the African Caribbean and European sample. Table 4 displays mean scores, standard deviations, and associated results from the between- and within-group ANOVAs for this sample.

Speaker race, partner race, and interaction effects. As predicted, there were significant differences in the use of assertion and affiliation associated with speaker race. European children were more assertive than both South Asian and African Caribbean children. Overall, South Asian children were more affiliative than European children, although there were no differences in levels of affiliation between African Caribbean and European children.

Tables 1 and 3 also indicate that there were effects of partner race on use of assertion and affiliation. In both samples, children use more affiliation when speaking with a partner who is South Asian and

Table 1

Values of t *and Effect Size (Cohen's* d*) for Speaker Race, Partner Race, and Interaction Effects Associated With the Use of Conversational Measures for South Asian and European Children*

	Speaker race		Partner race		Interaction	
	t	*d*	*t*	*d*	*t*	*d*
All children

Note. The means and associated statistics compare first race effects between same-race pairs (two South Asian children in a pair, SA – SA, and two European children in a pair, Eu – Eu) and then race effects between children in cross-race pairs (i.e., the South Asian child and the European child in SA – Eu). The degrees of freedom for the *t* tests are computed from the number of observations on which the means are based. In this study, that includes children in all-South Asian pairs (SA – SA, $n = 70$), children in all-European pairs (Eu – Eu, $n = 84$), South Asian children in SA – Eu ($n = 33$), and European in SA – Eu ($n = 33$). Proportion scores do not sum to 1.00 because some children offered no justifications and scored 0.
$^*p < .05$.

African Caribbean than when speaking with a partner who is European. Children also used more assertion when speaking with a South Asian partner compared with a European partner.

European children were more assertive than their African Caribbean partners in cross-race pairs, as indicated by a negative value for the associated interaction effect (see Table 3). However, there was no similar interaction effect among the South Asian and European sample. Levels of affiliation were higher in same-race than in cross-race pairs (see Tables 2 and 4). Additionally, race differences in the use of affiliation were greater comparing between same-race pairs than between each child in a cross-race pair.

Table 3
Values of t *and Effect Size (Cohen's* d*) for Speaker Race, Partner Race, and Interaction Effects Associated With the Use of Conversational Measures for African Caribbean and European Children*

Note. For speaker and partner race effects, a positive value of *t* indicates a higher score for African Caribbean than European children. A positive value of *t* in the interaction effect reflects a greater difference in same-race compared with cross-race pairs. The degrees of freedom for comparisons of speaker race, partner race, and interaction for the *t* tests are as follows: all children ($df = 204$), boys only ($df = 98$), girls only ($df = 106$).
$^{**}p < .01$. $^{***}p < .001$.

Assertion in cross-race pairs. To test our second hypothesis, we conducted independent *t* tests to compare the levels of assertion for each child in the cross-race pairs in each sample (i.e., SA – Eu and AC – Eu). Although mean scores in Tables 2 and 4 indicate that in cross-race pairs European children used more assertion than either their South Asian or African Caribbean partners, these differences were not significant.

Affiliation in same- versus cross-race pairs. The third hypothesis was that levels of affiliation would be higher in same- than in cross-race pairs. A one-way ANOVA was conducted for each sample comparing mean levels of affiliation in each pair type. For both samples, there was a small but significant effect of pair type on use of affiliation. In the South Asian and European sample, $F(2, 217) = 3.86$, $p < .05$, $\eta^2 = .03$, post hoc Tukey's honestly significant difference (HSD) tests ($p < .05$) indicated that there was significantly less affiliation in the cross-race pair (SA – Eu) compared with the all-South Asian pair (SA – SA). In the African Caribbean and European sample, $F(2, 205) =$

Girls														
Assertion	4.87	1.44	5.08	1.35	0.40	1, 68	.01	5.00	1.27	5.11	1.20	.09	1, 36	.00
Affiliation	4.38	1.41	3.31	1.18	11.91*	1, 68	.15	3.31	1.30	3.66	1.28	.70	1, 36	.02

Note. The means and associated statistics compare first race effects between same-race pairs (two African children in a pair, AC – AC, and two European children in a pair, Eu – Eu) and then race effects between children in cross-race pairs (i.e., the African child and the European child in AC – Eu). The degrees of freedom for the *t* tests are computed from the number of observations on which the means are based. In this study, that includes children in all-African pairs (AC – AC, $n = 64$), children in all-European pairs (Eu – Eu, $n = 74$), African children in AC – Eu ($n = 35$), and European in AC – Eu ($n = 35$). Proportion scores do not sum to 1.00 because some children offered no justifications and scored 0. $^\dagger p < .10$. $^* p < .05$.

3.11, $p < .05$, $\eta^2 = .03$, post hoc Tukey's HSD tests ($p < .05$) revealed a similar pattern with less affiliation in the cross-race (AC – Eu) pairs than in the all-African Caribbean pairs (AC – AC). Thus, levels of affiliation were lowest in the cross-race pairs in both samples and highest in the same-race minority pairs.

Gender, race, and conversation style. Tables 1 – 4 reveal that many overall effects of speaker race were reflected in the use of assertion and affiliation among boys and girls separately. European boys used more assertion than South Asian boys, but there was no effect of speaker race comparing African Caribbean and European boys and no effect of speaker race on boys' use of affiliation in either sample. Conversely, although there were no effects of speaker race on girls' use of assertion in either sample, both South Asian and African Caribbean girls used significantly more affiliation than European girls. Thus, overall effects of speaker race on the use of assertion stem largely from differences in boys' conversations, whereas effects of speaker race on the use of affiliation stem from differences in girls' conversations.

Breaking down the use of conversation measures by gender reveals further variation in partner race effects. Boys used more assertive speech when talking with South Asian and African Caribbean partners than with European children. For boys, there were no partner race effects in the use of affiliation. Girls were more assertive toward a European girl than toward a South Asian girl, whereas they were more affiliative when speaking with an African Caribbean compared with a European conversation partner.

Although there was no overall interaction effect in use of assertion in the South Asian and European sample, the interaction effect was significant for the boys and the girls considered separately (see again Table 3). Both these interaction effects indicate that racial differences in the use of assertion were greater within cross-race pairs than between same-race pairs. However, closer inspection of the means in Table 2 reveals that whereas in same-race pairs, levels of assertion are broadly similar, in cross-race pairs, European boys are more assertive whereas European girls are less assertive than their South Asian partners. In the African Caribbean and European sample, European boys used more assertion in cross-race pairs, but there was no interaction effect relating to girls' use of assertion in same-race and cross-race pairs. There were interaction effects for boys' and girls' use of affiliation in both samples. Once again, racial differences in the use of affiliation were greater between children from different race groups in the same-race pairs than in the cross-race pairs.

A further analysis was conducted for each gender group that matched the comparison of assertion in cross-race pairs for the whole sample. Independent *t* tests revealed a significant difference only between the South Asian and European boys, the latter using a higher level of assertion in the cross-race pairs, $t(28) = 3.01$, $p < .01$, Cohen's $d = 1.14$.

Finally, we compared levels of affiliation across pair types for boys and girls in each sample separately to see if there were differences between same-race and cross-race pairs. There were no significant effects of pair type in the South Asian and European sample. In the African Caribbean and European sample, there was a significant effect of pair type for the girls' sample, $F(2, 105) = 6.87$, $p < .01$, $\eta^2 = .12$. Post hoc Tukey's HSD tests ($p < .05$) indicated that the same-race pairs differed significantly (Eu – Eu vs. AC – AC), with the higher levels of affiliation in the African Caribbean pair.

Playmate Choices

The outcome measure in terms of playmate choice was the racial group of the child that the pair selected (European, South Asian or African) or, when children could not agree on an answer together, unresolved. In the present study, two specific predictions were made about playmate choice. The fourth hypothesis predicted that in same-race pairs, children would tend to choose a partner from the racial in-group. The fifth hypothesis predicted that in cross-race pairs, there would be fewer agreements about the choice of a playmate. Figure 1 shows the proportion of selections for different playmates by racial group. The association between a pair's racial composition and choice of playmate was significant for the South Asian and European group, $\chi^2(4, N = 110) = 43.47$, $p < .001$, Cramer's V = .31, and for the African Caribbean and European group, $\chi^2(4, N = 104) = 109.49$, $p < .001$, Cramer's V = .51.

Same-race pairs. In the South Asian and European sample, most Eu – Eu pairs (73.8%) selected a European child as a possible playmate, and most SA – SA pairs (57.1%) selected a South Asian child as a possible playmate. Although both of these selections reflect in-group preferences, it is worth noting that the proportion of children in the SA – SA pairs who made this in-group selection was lower than in the same-race Eu – Eu pairs. In the African Caribbean and European sample, most Eu – Eu pairs (91.9%) selected a European child as a preferred playmate. AC – AC pairs tended to choose an African Caribbean child as a preferred playmate (65.5%), and again, these minority-group pairs showed less marked in-group preference than the European majority pairs.

Cross-race pairs. In the cross-race pairs (SA – Eu), there was a relatively high proportion of unresolved conversations (27.3%). Almost half (48.5%) of the cross-race pairs selected a European child as a preferred playmate and fewer (24.2%) cross-race pairs selected a South Asian child. Cross-race pairs (AC – Eu) were also less successful in reaching an agreement about their choice of playmate (i.e., 37.1% of the conversations were unresolved). In these cross-race pairs, a European playmate (42.9%) was chosen more often than an African Caribbean playmate (20%).

Gender, race, and playmate choices. There were no significant gender differences in terms of the race of the chosen playmate, both between and within the two different samples.

Race, Conversation, and Playmate Choices

We proposed three hypotheses relating to the links between race, conversation, and playmate choices. The sixth hypothesis predicted that there would be high levels of assertion and low levels of affiliation in

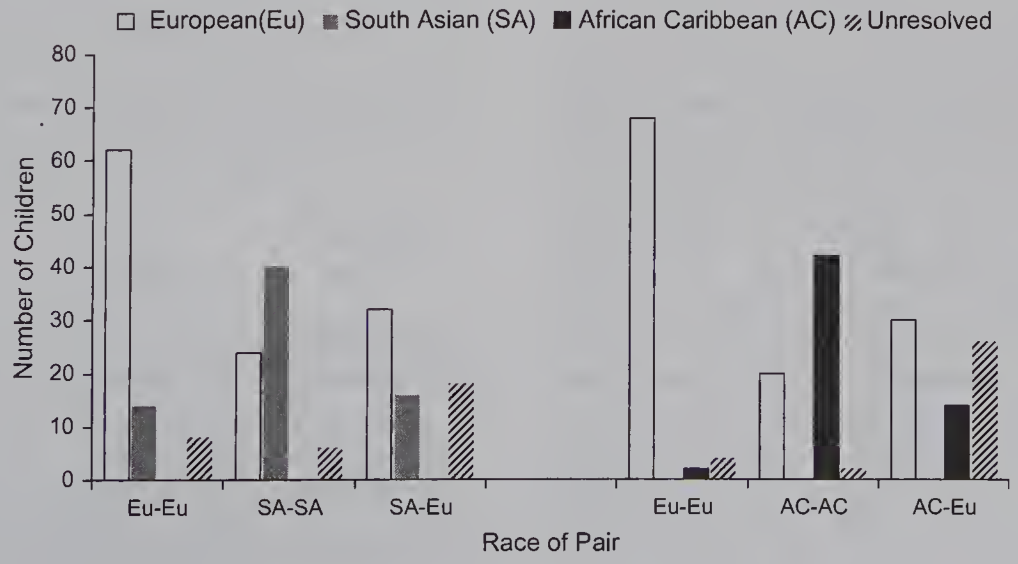

Figure 1. Children's choices of playmate by race and race of the pair.

$^{**}p < .01$. $^{***}p < .001$.

unresolved conversations. The seventh hypothesis predicted that same-race pairs who made an in-group choice of playmate would show high levels of affiliation. The eighth hypothesis predicted that in same-race pairs who made an out-group choice of playmate, there would be low levels of affiliation. Separate ANOVAs were conducted to examine the relations among pair composition, choice of playmate, and each of the conversation measures. Tables 5 and 6 present the mean levels of assertion and affiliation by conversation outcome (i.e., playmate choices), along with associated statistics, for the South Asian and European and African Caribbean and European samples, respectively. Tables 5 and 6 also show data and associated statistics broken down for each gender group.

Resolved and unresolved conversations. In both samples, variations in the use of assertion and affiliation were associated with the choices of playmate that pairs made. In the African Caribbean and European sample, levels of assertion were higher when conversations were unresolved than when both children agreed on a choice of playmate (although overall the effect was only marginally significant). In the South Asian and European sample, conversations that were unresolved were also associated with higher levels of assertion than when children agreed an answer. However, post hoc tests indicated that levels of assertion in unresolved conversations only differed significantly from conversations when children agreed on a South Asian playmate and not from when they agreed on a European playmate (see Table 5). In both samples, levels of affiliation were significantly lower in unresolved conversations than in conversations where children agreed a response together, which is consistent with the prediction made in the sixth hypothesis.

Affiliation and playmate choices. To test our seventh and eighth hypotheses, we examined the relation

Table 6

between playmate choice and levels of affiliation for same-race pairs only who agreed on a choice of playmate (i.e., resolved their conversations). Analysis of data from both samples indicated that there were no significant interactions among pair type, choice, and levels of affiliation.

Gender, race, conversation, and playmate choices. Results for boys and girls in each sample generally mirrored those for the sample overall. There were, however, some interesting variations. In the South Asian and European sample, boys used significantly less assertion when agreeing on a South Asian choice of playmate than when conversations were unresolved or children chose a European playmate. African Caribbean and European boys were most assertive when conversations were unresolved and least assertive when an African Caribbean or European playmate was selected. Although trends linking girls' use of assertion to conversation outcomes were similar across samples (i.e., higher levels of assertion in unresolved conversations than in resolved conversations), post hoc tests did not establish significant differences between groups.

Boys and girls in both samples used significantly less affiliation when conversations were unresolved than when they agreed on a choice of playmate together. Among girls in the African Caribbean and European sample, levels of affiliation were also significantly higher when a pair agreed to choose an African Caribbean playmate compared with when they chose a European playmate (see again Table 6).

Comparison of All-European Pairs From Both Samples

The existence of two separate samples (i.e., South Asian and European and African Caribbean and European) made it possible to compare the two sets of data for children in all-European pairs. This comparison constituted a check on the equivalence of the two samples. Separate independent t tests showed that there were no differences between the two samples on any of the dependent measures.

Discussion

The present study examined the influence of race on children's conversations about and choices of possible playmates. Three key research goals were (a) to identify the relations between race and children's conversational style, (b) to examine how race influenced children's playmate choices (i.e., conversation outcomes), and (c) to explore the relations among race, conversation style, and playmate choices. The findings indicate that race influences the style and outcomes of children's conversations about possible friends. Moreover, this influence is moderated by gender and varies according to the racial mix of the children involved in interaction.

Our initial set of hypotheses focused on the relation between the race and the style or social dynamics of children's conversations. The first hypothesis was confirmed. That is, a child's race influences the levels of assertion and affiliation the child uses in a conversation. Specifically, European children were more assertive than South Asian and African Caribbean children. South Asian children were more affiliative than European children, but there was no difference in levels of affiliation between European and African Caribbean children. These effects of speaker race indicate that there are different conversational styles that are linked to race among children at this age, perhaps as a result of different socialization experiences associated with membership of different race groups. Thus, it could be that European children learn a more assertive conversational style from interactions with parents, peers, and others (who will often be members of the racial in-group), whereas South Asian children learn to be more affiliative than children from the other racial groups that were studied here. Hughes et al. (2006) have noted that ethnic socialization can be one way in which many minority parents seek to raise socially competent children in a racialized society. Children's conversational styles may also be affected by observing others in wider society or in the children's own cross-race interactions that entail different contexts for socialization for children from different racial groups. The present study indicates that, by 7 years of age, children from different racial groups have learned to reproduce these different conversational styles in interaction with their peers.

We found no support for our second hypothesis that, as a consequence of status differences between children from majority and minority groups, European (i.e., majority group) children would be more assertive than African Caribbean and South Asian (i.e., minority group) children in cross-race interaction. A simple explanation may be that children did not perceive status differences between the racial groups. However, it seems unlikely that children at this age are unaware of status differences associated with race. By middle childhood, children recognize that minority ethnic groups are associated with different stereotypes and that there are differences in relative status between minority groups (Davis, Leman, & Barrett, 2007; Lam & Leman, 2003). Moreover, our results do not show that children fail to respond to the race of a conversation partner or to the racial mix of children involved in interaction. On the contrary, there were numerous variations in children's use of affiliation and assertion linked to race. All children were more assertive with a South Asian partner, and more affiliative with a South Asian or African Caribbean partner, than with a European child. In the South Asian and European sample, race differences in children's use of affiliation were greater comparing same-race with cross-race pairs. This finding suggests that children responded to the dynamics of in-group and out-group interaction. In the African Caribbean and European sample, race differences in assertion were more marked in same-race pairs, whereas race differences in affiliation were more marked comparing same-race pairs. Thus, children were sensitive to the race of their partner, and these effects were visible in conversation. However, it was not the case that this resulted in majority-group children being more assertive toward minority-group children in conversation.

The failure to find support for the second hypothesis suggests that, in terms of conversation at least, it is not straightforwardly the case that racial majority children will dominate or assert themselves over minority-group children. Additionally, although European children may have a more assertive conversational style generally, this assertion does not appear to be deployed to a greater or lesser extent when speaking with a minority-group partner. It should be noted, however, that in the present study, the participating children came almost exclusively from highly ethnically heterogeneous and low-income neighborhoods, and their schools celebrated this racial diversity. In another context (or at another point in development), levels of assertion in conversations between majority- and minority-group children might not be so balanced.

Although status differences do not appear to affect levels of assertion in cross-race interaction, a key tenet of work on intergroup dynamics is that individuals affiliate more with members of their in-group than with members of an out-group (Tajfel & Turner, 1986). We thus proposed a third hypothesis that predicted higher levels of affiliation in same-race pairs than in cross-race pairs. Our third hypothesis was partly supported. In both samples, children were more affiliative in minority same-race than in cross-race pairs. The mean levels of affiliation of same-race majority pairs were somewhere in between those of cross-race pairs and same-race minority pairs, but this trend did not reach significance and generally effect sizes were rather small.

Higher levels of affiliation in minority pairs may be a general phenomenon or a consequence of using playmate choice as the topic of discussion in the present study. In this respect, it is possible that minority children felt the race-related aspects of this task more intensely than majority children because of its connotations for real-life friendship choices and intergroup contact. Race may be a more salient feature of friendship choice to minority-group children at this age because of their more negative social experiences or because of a more hostile social environment (Brown & Bigler, 2005; Spencer, Cunningham, & Swanson, 1995). The present study opens the possibility that racial cleavage in friendships and playmate choices that has been observed in naturalistic studies from preschool onward (Finkelstein & Haskins, 1983) may be associated with particular interpersonal dynamics between children. Of course, a question remains whether these features of interaction are causes or consequences of this racial cleavage.

A further intriguing finding to emerge from the present study was that race affects conversations differently for boys and girls. European boys were more assertive than both their African Caribbean and South Asian contemporaries. African Caribbean and South Asian girls were more affiliative than European girls. One interpretation of these effects of speaker race is that these differences in conversational style stem from the distinct socialization experiences of boys and girls from different racial groups. European boys may learn to be more assertive than African Caribbean and South Asian boys, and African Caribbean and South Asian girls may learn to be more affiliative than European girls.

When cross-race pairs (i.e., African Caribbean and European pairs and South Asian and European pairs) and same-race pairs (i.e., all-African Caribbean, all-South Asian, and all-European pairs) were compared, there were also differences in the conversation style that were linked to the race of a child's conversation partner. In terms of assertion, the influence of race in boys' conversations divided along majority–minority racial lines. European boys (i.e., the majority group) were more assertive than African Caribbean and South Asian boys (i.e., the minority groups), but this difference was especially marked in cross-race interactions. In other words, the influence of race in boys' conversations led to more asymmetry in levels of assertion when boys talked with boys from a different race group. This finding supports the observation that preschool boys' interactions are more dominance oriented than girls' interactions (Leaper & Smith, 2004) and that these differences continue into adulthood (Sidanius, Levin, Liu, & Pratto, 2000). It may be that, at 7 years of age, race constitutes a source of social status or asymmetry that fits easily into the dominance-oriented dynamics of boys' conversations.

In contrast to the boys, girls from all racial groups were more assertive toward a European conversation partner. In South Asian and European pairs, the European girls displayed very low levels of assertion. Compared with boys', assertion is less of a feature of girls' interactions (Leaper & Smith, 2004), and so may be considered a more negative characteristic in girls' discussions. By avoiding assertion, European girls may be positioning themselves (or are being positioned) closer to a gender norm in conversation, that is, inviting agreement rather than demanding it (see Leman et al., 2005). South Asian and African Caribbean girls were more affiliative speakers, and all the girls were more affiliative with an African Caribbean girl, which corresponds to the finding that children tend to give higher companionship and friendliness ratings to African Caribbean girls than to other race and gender groups (Aboud et al., 2003). The differences between the races were greatest when comparing levels of affiliation across same-race pairs than when comparing within cross-race pairs.

Our second set of hypotheses concerned children's choices of playmate. The fourth hypothesis, which predicted that same-race pairs would be more likely to choose a playmate from their racial in-group, was confirmed for all three racial groups. In some senses, this finding should not be surprising given that playmate preference delineates along racial lines from a very young age (see Finkelstein & Haskins, 1983); however, in-group preference was notably less pronounced in same-race minority pairs (i.e., African Caribbean or South Asian) than in same-race majority pairs (i.e., European). This fits with the results of some recent studies (Margie, Killen, Sinno, & McGlothlin, 2005; McGlothlin et al., 2005) indicating that U.S. minority-group children are more likely than majority-group children to think peers from different racial groups can be friends. As predicted by the fifth hypothesis, cross-race pairs had more difficulty reaching an agreement about the choice of a playmate than same-race pairs. This was probably because of conflicting in-group choices. When children in cross-race pairs agreed on a choice, most pairs opted for a European child as their preferred playmate.

These results are reminiscent of previous research (e.g., Aboud, 1988; Spencer & Markstrom-Adams, 1990) that suggested that minority-group children exhibit less preference for their own racial group compared to majority-group children. Our findings also fit with previous work that used attitude measures outside the context of race and identified more in-group bias in high- (than low-) status groups of children between 7 and 12 years of age (Bigler, Brown, & Markell, 2001). In this case, perhaps racial minority children desire a playmate from a higher status group (and perceive Europeans to be higher status). Our conversational paradigm is a novel means of eliciting information about children's racial understanding that can inform studies of racial attitudes and identification.

Our last set of hypotheses explored the links among race, conversations, and playmate choices. The sixth hypothesis was confirmed and, as predicted, there were higher levels of assertion and lower levels of affiliation in unresolved conversations. This finding underscores the predicted role of assertion and affiliation in decision-making processes. Children who are unable to agree will simply reassert their preference and continued disagreement leads children to disaffiliate.

Analysis of the data did not, however, confirm the seventh and eighth hypotheses. These predicted, respectively, that there would be high levels of affiliation when same-race pairs agreed on an in-group playmate and low levels of affiliation when same-race pairs agreed on an out-group playmate. At first glance, this finding suggests that our attempt to identify a link between conversation, intergroup dynamics, and decision making has failed. Indeed, it may be that while the race of a pair influences which playmate the pair chooses, levels of affiliation in conversation do not correlate with this decision. However, it should be noted that very few children in same-race pairs chose an out-group playmate, and a larger sample size may have revealed some significant effects. Moreover, in-group and out-group biases in adults may, sometimes unknowingly, affect decision-making processes and friendship choices (Mackie & Ahn, 1998). In the present study, given how lengthy children's discussion were, it seems surprising that intergroup dynamics did not affect affiliation and, in turn, children's friendships choices. Further work is needed to establish the ways in which race, conversation, and friendship choices interrelate because it is through conversation and discussion that meaningful contact between children happens.

Some caution should be applied when extending these findings to *all* interactions and playmate choices. In the present study, children were drawn from a school with a heterogeneous mix of races. Although this mix mirrors many contemporary urban environments, the findings from this study may be different in other sociocultural contexts and with other racial groups. Moreover, other factors may influence conversation dynamics between children. For example, Brown and Bigler (2002) found several different effects of minority status on intergroup attitudes that were related to the size, salience, and status of the groups as well as children's ages and the measures employed. Our findings and those of other studies suggest that these and other factors may also relate to variations in conversation dynamics. Indeed, the context in which conversations happen provides not only a backdrop to those discussions but also has the potential to act as a further influence on the dynamics of those conversations. From a practical perspective, interventions seeking to reduce racial prejudice need to be mindful of these broader influences on attitudes and behavior, as well as the specifics of conversations that were explored here.

In terms of intergroup relations, the quality of conversation in the cross-race pairs is of particular interest because contact between children of different races has been suggested as a way to improve intergroup relations, reduce prejudice, and foster positive intergroup attitudes (Pettigrew & Tropp, 2006). In our cross-race pairs, children had some difficulty agreeing on a choice of playmate, and when they did agree, they more often settled on a European (majority group) child rather than a South Asian or African Caribbean (minority group) child. Our findings suggest that interventions focusing on contact between children from different races (see Cameron et al., 2006) need to focus not only on achieving contact but also on guiding that contact in ways that challenge children's existing friendship preferences to ensure sustained interaction between children from different groups. Particular attention needs to be paid to fostering affiliative interactions in cross-race pairs. In this respect, our friendship task certainly did not encourage affiliation, given that the task pitted children's in-group preferences against one another. Other, racially neutral tasks—for instance, free play, problem solving, or collaborative learning tasks—may provide better opportunities for children from different racial groups to affiliate. Such opportunities are needed to address the racial cleavage in friendship and playmate choices in place early in childhood and continuing through to adulthood (Hallinan, 1982). The present study demonstrates not only that race affects children's choices of playmate at 7 years but also that race is a powerful force that affects the style and dynamics of children's conversations.

Where Is the Essence? Developmental Shifts in Children's Beliefs About Internal Features

George E. Newman and Frank C. Keil
Yale University

The present studies investigated children's and adults' intuitive beliefs about the physical nature of essences. Adults and children (ranging in age from 6 to 10 years old) were asked to reason about 2 different ways of determining an unknown object's category: taking a tiny internal sample from any part of the object (distributed view of essence) or taking a sample from one specific region (localized view of essence). Results from 3 studies indicated that adults strongly endorsed the distributed view, and children showed a developmental shift from a localized to distributed view with increasing age. These results suggest that even children go beyond mere placeholder notions of essence, committing to conceptual frameworks of how essences might be physically instantiated.

Adults and children alike seem to believe that many sorts of things have essences. In its everyday sense, an essence is often thought of as something intrinsic to an entity that causes that entity to be the kind of thing that it is. For example, the essence of a tiger would be some unique characteristic, such as DNA, that is shared by all tigers and causes tigers to have their distinct tiger properties (Sober, 1994). Such beliefs are part of a cognitive bias known as "psychological essentialism" (Medin & Ortony, 1989), a bias that not only embraces the notion of an essence but also the idea that this deep, underlying nature is somehow causally responsible for an entity's category membership and its phenomenal properties (Gelman, 2003).

Much of the support for psychological essentialism comes from studies with young children. For example, children as young as 4 years old appear to understand that internal causes are more to likely determine an objects' behavior and appearance than are external ones (Gelman, 2003; Gottfried & Gelman, 2005; Inagaki & Hatano, 2002; Sobel, Yoachim, Gopnik, Meltzoff, & Blumenthal, 2007), and they are likely to view internal properties as vital to determining an animal's category membership (Gelman & Wellman, 1991; Keil, 1989). Young children will also extend internal, nonvisible features to novel category instances (e.g., Gelman & Coley, 1990; Gelman & Markman, 1987). For example, if children are taught a property about leaf insects, they are likely to generalize that property to similarly named organisms (other insects) instead of similar-looking objects (other leaves), even when surface appearance conflicts with category membership (Gelman & Markman, 1987).

The emergence of such reasoning in young children underscores the strength of essentialist commitments. Yet, the ease with which children seem to reference internal, nonvisible features presents somewhat of a dilemma. As adults, we are at least familiar with the concepts of cells, molecules, and DNA. Thus, there is at least some basis for essentialist beliefs to be grounded in real, physical structures—even if those connections to reality are often inaccurate (Hull, 1965; Keil & Richardson, 1999; Mayr, 1982). But for children as young as 4 or 5, who presumably know nothing about such structures, it is unclear what type of representation they are using to guide their inferences about these unseen, internal properties. In other words, in the absence of concrete theories about actual biological mechanisms, what does it mean to take an essentialist stance?

Some researchers have suggested that essences are understood more as causal "placeholders," rather than as actual physical entities (Gelman, 2003; Medin & Ortony, 1989). Thus, one could believe that there is some underlying property that unites category members, without knowing exactly what that property actually is or where it might be located. It might be that for young children—and for that matter, many adults—psychological essentialism consists of nothing more than the belief that certain kinds of entities,

such as animals, have essences, and that those essences are somehow causally responsible for each member of a kind sharing certain properties. In this "barest placeholder" sense, the child is completely agnostic about particular causal relationships or mechanism and believes nothing beyond the very general idea that essences cause surface properties in ways that remain completely mysterious (see Strevens, 2000, for a more detailed account of different notions of psychological essentialism).

An alternative to the barest placeholder account would argue that even though children clearly do not have knowledge about specific biological mechanism such as genes and gene regulation, they still might possess much more abstract hunches about likely causal pathways and patterns through which essences have their effects. There is ample precedent for the idea that young children, even preschoolers, can have abstract expectations about causal patterns in a domain while not having any idea about specific mechanism (Inagaki & Hatano, 2002; Kalish & Gelman, 1992; Simons & Keil, 1995). For example, children expect animals and machines to have different insides even when they lack specific predictions about what those insides should look like (Simons & Keil, 1995). By this account, even if young children obviously do not know anything about DNA or the molecular basis of gene expression, they still might have some skeletal hunches about the ways in which essences are physically manifested.

Moreover, there is evidence to suggest that children may often conceive of essences as "very tiny, internally located" structures. For example, Springer and Keil (1991) found that if young children are asked to describe how various types of properties might be transmitted from parents to offspring, they are likely to endorse "Gemmulic" theories of biological transmission. In these studies, children reported, for example, that when a brown mother dog has a puppy, the puppy is likely to be brown because, "some very tiny brown pieces went from the mother to the puppy, . . . got into the puppy's skin, and the puppy turned brown." Springer and Keil derived the name "gemmules" from early theories in biology that proposed that the fetus inherits tiny pieces or copies of organs emanating from its mother's body (Appleman, 1979; Mayr, 1982).

The aim of the present studies was to investigate whether children (and adults) may go beyond the barest placeholder sense of essence, to make auxiliary assumptions about the way in which essences are physically realized within an entity. For obvious reasons, it is difficult to directly ask children and adults about the physical nature of essences because people rarely refer to the concept of "essence" per se. Instead, similar to previous work (e.g., Keil, 1989), the present studies used "discovery" scenarios in which the category of an object is unknown, and participants must decide the best way to identify that object's category. This method assumes that beliefs about the category-identifying feature (a feature that is specific to one particular kind and no other) should map onto beliefs about the essential feature (a feature that causes one kind to be different from all others).

This method is about identifying categories, not individuals. With individuals, idiosyncratic surface features are often paramount. A person's tattoo, fingerprint, or dental work may be all one needs to confidently identify a person, even though those marks are not at all considered central to the individual. With categories, however, it is far less common to assume that there is some sort of causally irrelevant "accidental" marker of category membership. To be sure, surface traits can indicate category membership, but we assume they work because they are lawful products of internal causes. Hence, the focus on categories in these studies avoids some concerns about idiosyncratic surface properties that might arise for individuals. In addition, by focusing exclusively on internal parts, we are selecting just those properties that prior work has argued as closest to beliefs about internal determinants of kind (e.g., Gelman, 2003; Keil, 1989).

So, what sorts of assumptions might children make about the physical nature of essences? Adults, for instance, tend to believe there are kind-specific microscopic structures (DNA and molecules) that are common to members of naturally occurring categories. For living kinds, such beliefs may actually be inaccurate as the actual genetic basis of a species is always a probabilistic distribution of highly similar but not identical genetic sequences (Hull, 1965; Keil & Richardson, 1999; Mayr, 1982). Moreover, adults often appreciate that the same microstructure is homogeneously distributed throughout an organism—for instance, that the DNA in my finger is the same as the DNA in my stomach—even though they may not fully appreciate how microstructure in these different locations is responsible for morphological differences. One way to characterize such beliefs is that they reflect a "distributed" notion of essential features—that is, that members of a category share a common feature, which is distributed throughout the inside of each category member. Thus, despite the existence of different internal structures within a particular entity (e.g., the heart, the brain, or the lungs), the same essential feature (DNA) is present throughout. In terms of categorization, because the critical feature is distributed, samples from any internal location should be capable of identifying its kind; a sample from one part should be as equally identifying of category membership as a sample from another part.

Assuming that adults' beliefs about the essential features of natural kinds are best characterized as *distributed*—a possibility we explored in the first study—a critical question is, how do beliefs about distributed essence develop? Do children constrain their inferences about essential features in a manner similar to adults?

It may be that for natural kinds, children instead tend to think of the essential feature as a single entity that is located in one special place. This "localist" notion of essential features might be analogous to the idea that there is a "seat of soul" such as the pineal (Bloom, 2004; Descartes, 1985), a highly focal point out of which causal effects emanate. Thus, rather than thinking of essential features as distributed throughout an entity, children may think that there is a single focal place within an object that determines category membership. This view might predict that, unlike the distributed account, there could be only one location where one could look to identify the category of an object. In all the three studies, we contrasted the distributed view against the localized view to determine how children of different ages and adults may think about the physical nature of essences.

If children do make some assumptions about how identifying features are physically realized within an object, a second critical question asks about the domain specificity of those notions. Consider first the contrast between biological kinds and other nonliving natural kinds. There is broad consensus that both are thought to possess essential features (e.g., Ahn et al., 2001; Medin & Ortony, 1989; Putnam, 1975; but also see Malt, 1994; Strevens, 2000 for alternative accounts); but the nature of those features is quite different. Cut a piece of gold into any number of pieces and all pieces are "essentially" the same. Cut a dog into small pieces (only as a thought experiment, please), and it is still clear that most pieces will be very different from each other. Indeed, most nonbiological kinds (e.g., elements such as gold and sulfur, compounds such as water and jade, and mixtures such as dirt and sand) are normally considered to have homogeneous internal structures. Such things are normally substances that take mass nouns—although, not necessarily (e.g., an icicle or a snowflake). In comparison, living kinds are predominately bounded entities with heterogeneous internal structures and take count nouns; only with a layer of more sophisticated biological knowledge, do the deeper commonalities in all biological tissue in an organism become apparent.

Because of this major contrast and because very young children do have a clear sense of count/mass distinctions as well as a some notions about substances (e.g., Au, Romo, & DeWitt, 1999; Dickinson, 1987; Stavy, 1991), our first two studies contrast living and nonliving natural kinds. Because even a modest amount of experience with broken up pieces of rocks or minerals would reveal that nonliving natural kinds are homogeneous, a shift to a distributed view of essences might occur earlier in development for homogenous substances than for living kinds and in fact might be a basis for later emerging analogous notions about living kinds. Using the method outlined above, our first two studies compare beliefs about essential features for living kinds with beliefs about essential features for nonliving natural kinds.

A second major contrast is between all natural kinds and artifacts. It is controversial whether artifacts should even be thought of having essential features anything like those of natural kinds. For example, they have been argued to either have no essences (Sloman & Malt, 2003) or to have essences in the form of the intended category of their creators (Bloom, 2004). Moreover, given sharply divergent intuitions among elementary school children about the relevance of surface properties to category membership of artifacts versus natural kinds (Gelman, 1988; Keil, 1989), the artifact/natural kind divide may reveal contrasting intuitions about distributed versus localized accounts. Our third study explores this contrast while also using a converging method to explore the generality of the first two studies. In particular, we predict that it would be implausible at any age to have a distributed view of artifacts (other than for synthesized substances such as plastics).

In short, these studies use intuitions about features needed for categorization (identifying features) as a way of asking whether young children merely believe in essential features that somehow determine category membership in a completely unspecified manner or whether they also embed their sense of essential features in a more constraining framework that specifies how those features are physically realized within objects. We predict that even young children will show judgments that go beyond barest placeholder notions. We further predict that these intuitions will vary across broad domains such as substances, living kinds, and artifacts, with distributed views emerging first for substances, then for living kinds, and never for artifacts.

Experiment 1

The purpose of Experiment 1 was to determine whether the distinction between the distributed versus the localist accounts was a psychologically useful one, and second, whether adults show any strong endorsement of either view.

Method

Participants. Thirty-one undergraduates participated in exchange for course credit.

Stimulus materials and procedure. In a within-subjects design, participants were given questionnaires that described a situation in which scientists discovered objects whose category was unknown. They read, for example:

> Many years ago, a giant glacier moved across the land and froze some things inside. A group of scientists discover the glacier and they notice that a large animal is frozen inside. They want to know what kind of animal it is. The scientists decide that they will take really tiny pieces from the inside of the animal. Each piece will be about the size of a pea, and then the scientists will use all their tools and technology to look at these tiny pieces, and they will be able to see everything that is inside each piece.

Participants were then asked to rate the degree to which they agreed with the each of the following statements:

1. "It doesn't matter where they take the pieces from, any piece will be able to tell them what kind of animal it is" (distributed statement).
2. "There is only one special piece that will tell them what kind of animal it is" (localized statement).

For four different natural objects (a large animal, a small animal, a rock, and a piece of metal), participants rated on a 0–9 scale (where higher numbers denoted greater agreement) the degree to which they agreed with the distributed and localized statements. The wording was similar for each item except that the words "small animal," "rock," and "piece of metal" were substituted as appropriate. We created four different versions of the survey that varied the order in which the different scenarios were presented as well as whether the localized or distributed statement appeared first.

Results

The results from Experiment 1 are reported in Table 1. Adult participants were overwhelmingly more likely to agree with the distributed approach, as confirmed by a mixed-model analysis of variance (ANOVA) with statement type (distributed vs. localized) and object type (animal vs. substance) as within-subjects factors. This analysis revealed a significant main effect of statement type on participants' ratings, $F(1, 30) = 128.69$, $p < .001$, partial $\eta^2 = .811$; as predicted, participants were more likely to agree with the distributed statement ($M = 6.93$, $SE = .27$) than with the localized statement ($M = 1.34$, $SE = .26$). We also observed a significant main effect of object type, $F(1, 30) = 10.78$, $p = .003$, partial $\eta^2 = .264$; participants gave higher ratings to substances ($M = 4.41$, $SE = .09$) than to animals ($M = 3.85$, $SE = .17$). We also found a significant interaction between statement type and object type, $F(1, 30) = 6.98$, $p < .05$, partial $\eta^2 = .188$. This interaction was driven by differences in ratings of the distributed statement. Participants were more likely to agree with the distributed statement for substances ($M = 7.59$, $SE = .27$) than for animals ($M = 6.27$, $SE = .40$), $t(30) = 3.22$, $p < .01$. Agreement with the localized statements, however, was not significantly different between items ($p = .62$). We ran an additional ANOVA that included which survey version participants completed (i.e., presentation order) as a between-subjects factor. There were no main effects or interactions of presentation order on participants' ratings ($F < 1$).

Table 1
Mean Agreement (Standard Deviation) With Localized and Distributed Statements for Each Item in Experiment 1

Item	Localized	Distributed
Large animal	1.40 (1.61)	6.40 (2.25)
Small animal	1.47 (1.79)	6.15 (2.57)
Rock	1.26 (1.65)	7.19 (2.01)
Metal	1.21 (1.67)	7.98 (1.36)

Note. Judgments were made on a 0–9 scale, where higher numbers denoted greater agreement.

Agreement with distributed statements was negatively correlated with agreement with localized statements (for substance items, $r = -.79$, $p < .001$; for animal items, $r = -.52$, $p < .01$).

Discussion

The results indicated that there is strong agreement among adults about the physical nature of essential features. Adults appear to think of such features as distributed throughout the inside of natural kinds and not localized to one particular region or part.

We also observed a significant interaction between statement type and object type. Adults were more likely to agree with distributed statements that referred to substances than distributed statements that referred to animals. One interpretation of this result is that substances are simply known to be more internally homogenous than animals, and the interaction with object type reflected this difference. Another interpretation might be that although adults overwhelmingly endorse distributed views for both animals and substances, they could still think of the essential features of animals as more localized. In other words, though adults have explicitly learned that the internal causal property in animals (DNA) is distributed, perhaps more developmentally primitive ways of viewing these structures (i.e., localist notions) still compete with this view. Therefore, data from children (Experiments 2 and 3) may shed light on this issue, as they provide an important comparison not only for when distributed notions develop but also what types of knowledge might be used to support such beliefs. If, for example, children think of substances as distributed before animals, it may because they use their knowledge about homogeneous substances to support more complicated inferences about the underlying essence of living kinds.

Experiment 2

The purpose of Experiment 2 was to explore when distributed views of essential features develop and any potential differences between substances and animals. We adapted the adult procedure from Experiment 1 to be suitable for elementary school children. We tested elementary school children as a way of dissociating the degree to which notions of distributed microstructure might stem from explicit knowledge about actual microstructure (DNA and molecules) versus more naïve assumptions about the nature of natural kinds. Presumably, all our adult participants (college undergraduates) had been exposed to the concepts of DNA and molecules in some formal sense. However, children are typically not exposed to these concepts in school until sixth- and seventh-grade biology and chemistry, and it is not typically until high school that children learn about the periodic table or biological processes such as cell division, genetic recombination, and so forth. This of course does not rule out the possibility of our participants' learning about DNA from other sources, such as parents, older siblings, or television crime shows. It does, however, limit the degree to which children have formally learned, for instance, that DNA consists of chromosomes and base pairs, which are replicated in every cell in the body. Thus, it is fair to say that children and our sample of college adults were substantially different in terms of their explicit knowledge about actual microscopic bodies.

Method

Participants. Participants were 67 children, including 20 kindergarteners (*M* age = 6.0, range = 5.6–6.7), 23 second graders (*M* age = 8.1, range = 7.7–8.6 months), and 24 fourth graders (*M* age = 10.2, range = 9.7–10.7 months), each of whom was interviewed individually. An additional 9 students were tested but did not complete the session. Altogether there were 36 boys and 31 girls, roughly evenly distributed across grade. Participants were from middle- and upper-middle-class backgrounds and were recruited at public and private elementary schools. Ethnicity breakdowns were as follows: Asian (*n* = 41), Caucasian (*n* = 21), Hispanic (*n* = 4), and African American (*n* = 1). A polling of the teachers confirmed that children were not receiving instruction about DNA or chemical elements in class.

Stimulus materials and procedure. Participants were first shown a picture that depicted a large block of ice with objects frozen inside. The objects were created to loosely resemble four different natural objects (identical to Experiment 1). The experimenter said:

> Many years ago a giant block of ice moved across the land and froze some things inside. A group of scientists discover the block of ice and they want to know what kinds of things are frozen inside.

Participants were then presented with a card that "zoomed in" on one of the objects. The experimenter then said:

> Scientists discover that a large animal is inside the block of ice and they want to know what kind of animal it is. To figure it out, the scientists decide that they will take really tiny pieces from the inside of the animal. Each piece is really, really, tiny. It's about the size of a pea. The scientists will use all their tools and technology to look at these tiny pieces, and they can see everything that is inside each piece.

Participants were then shown two pictures of scientists thinking about the tiny pieces (see Figure 1). The experimenter said:

> There is a disagreement between the two scientists. One scientist thinks that it doesn't matter which piece they look at to figure out what kind of animal it is, because any of the pieces they look at can tell

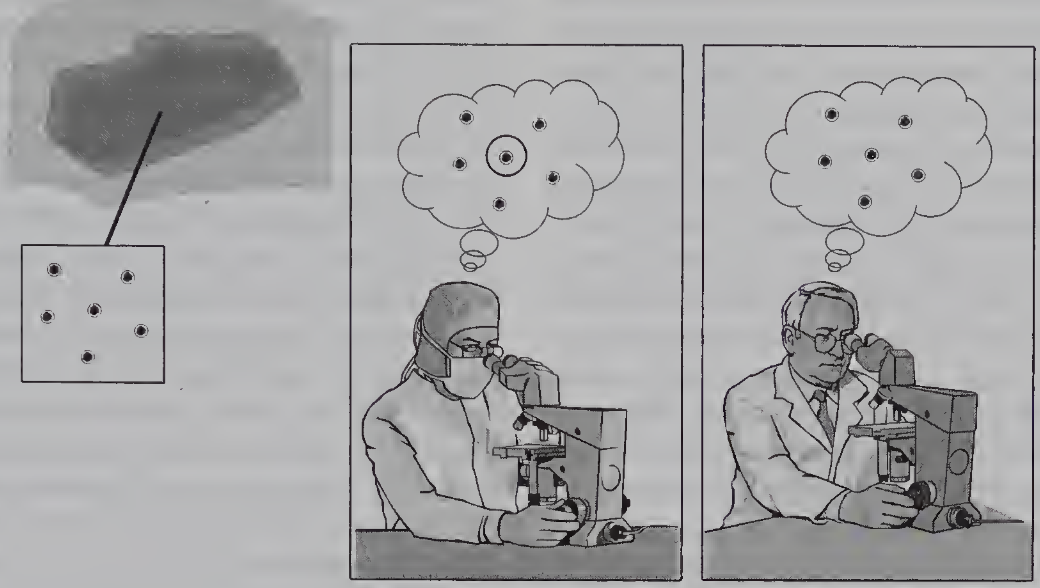

Figure 1. Sample pictures used in Experiment 2.

> them. But the other scientist thinks that there is only one piece that can tell them about what kind of animal it is, and they must find that one piece to figure it out.

Participants were asked to decide which scientist they thought was correct. After they responded, either verbally or by pointing, they were also asked to explain why they chose that answer. This process was repeated for the remaining three items (a small animal, a rock, and a piece of metal). The protocol was similar for each item, except that the words "small animal," "rock," and "piece of metal" were substituted as appropriate. The order in which the statements were presented was balanced within each participant so that for half of the items, a child was given the distributed statement first (any piece can tell them), whereas for the other half of the items, the localized statement (only one piece can tell them) was presented first. Additionally, two sets of distributed and localized images were created (where we crossed which scientist was pictured with which statement type), so that children did not respond on the basis of which scientist looked more knowledgeable. Materials were presented in one of the four different randomized orders that varied the sequence in which each item occurred.

Participants also completed an item at the end of each session that asked about distributed microstructure more generally. The experimenter said:

> Today in school, Molly and Erica learned about what makes an animal be a certain kind of animal. Their teacher told them about what makes a dog be a dog, a cat be a cat, and a mouse be a mouse. After school, Molly and Erica are trying to remember what they learned. Molly says that what makes an animal be a certain kind of animal is one special piece that is buried deep inside. Erica says that what makes an animal be a certain kind of animal is spread out through the entire body of animal.

Participants were asked to decide which person they thought was correct. The order of the distributed and localized statements, as well as which name was paired with which option, was balanced across participants.

Results

For each item, children's responses were classified as either distributed (i.e., *any location can identify the object*—coded as 1) or localist (i.e., *only one location can identify the object*—coded as 0). This produced five data points for each child (one for each item).

Two separate analyses were performed. We first examined the data nonparametrically. There were significant differences in the pattern of responses between the age groups for the "small animal," $\chi^2(2) = 7.52$, $p < .05$; "rock," $\chi^2(2) = 12.03$, $p < .01$; and "metal," $\chi^2(2) = 10.30$, $p < .01$ items. We then looked at each age group separately. Fourth graders were significantly more likely to choose the distributed option over the localized option for the "metal" and "rock" items ($p < .01$) and showed the same marginally significant pattern for the "large animal" and "kind-identity" items ($p = .06$) via binomial tests (two-tailed). Second graders' responses did not differ from chance (all $p > .38$). Kindergarteners, on the other hand, were more likely to choose the localized option over the distributed option for the "small animal" item ($p < .05$) via a binomial test (two-tailed), but did not show significant differences on any of the other items (all $p > .82$). These results are reported in Table 2.

In a second analysis, we summed the scores from all items to produce a score that ranged from 0 *localist response on all items*) to 5 (*distributed response on all items*); see the Appendix for a distribution of these parametric scores. A one-way ANOVA of this combined score comparing the three age groups revealed a significant main effect of grade on children's responses, $F(2, 64) = 9.86$, $p < .001$. Bonferroni post hoc analyses revealed that fourth graders were significantly more likely to endorse a distributed account ($M = 3.75$, $SE = .23$) than either second graders ($M = 2.43$, $SE = .27$), $p = .001$, or kindergarteners ($M = 2.20$, $SE = .32$), $p < .001$. Second graders and kindergarteners were not significantly different from one another. Comparisons to chance responding ($M = 2.5$), revealed that only fourth graders were significantly different than chance, $t(23) = 5.50$, $p < .001$.

Overall, children's justifications were too infrequent and sporadic to be coded and analyzed. However, only one child (age 10 years 7 months) used DNA to explain their response and a second child (age 10 years 4 months) mentioned cells.

Discussion

Results from Experiment 2 indicate that by at least fourth grade, children, like adults, tend to hold a distributed view of essence. These children reported that the unknown object's category could be determined by looking "anywhere," rather than in one specific location. Moreover, such beliefs do not appear to directly stem from knowledge about DNA or molecules because children hardly ever referred to these concepts. At the same time, fourth graders' responding was not identical across items. Endorsement of the distributed option for substances (rocks and minerals) was robustly above chance responding, whereas endorsement of the distributed option for animal items (small animal and large animal) only trended in that direction or was weakly significant. This pattern is interesting because it dovetails with the patterns observed in adults. Both adults and fourth graders tended to show weaker endorsement of the distributed option for animals compared to substances. As hypothesized before, this could be because a distributed understanding of complex, heterogeneous biological systems, such as animals, stems from a distributed understanding of less complicated, homogeneous structures, such as minerals. We return this issue at greater length in the General Discussion section.

The differences we found between fourth graders and younger children could be interpreted in one of the two ways: It could be that younger children simply do not have reliable intuitions about the physical nature of "very tiny internal pieces"; thus, they were at chance responding throughout. However, it may also be that younger children hold a consistent but competing view that we did not adequately measure with this task—namely, that *there is* one special piece that informs categorical identity better than others. Such an interpretation is at least plausible given that kindergarteners did favor this response at above chance levels for at least one item. Additionally, some of the younger children's justifications for selecting the localized option supported this view as well. For example, a few children spontaneously reported that the scientist would know best by looking "in the middle," whereas others offered structures such as "the blood" or "the heart." It could be that younger children really do tend toward a localist view of identifying internal properties, but the difficulty of the task obscured this pattern. In Experiment 3, we explored this issue further by creating a different scenario that simplified some of the task demands from Experiment 2.

Table 2
Proportion of Children in Each Age Group Choosing the Distributed Option in Experiment 2

Item	Kindergarten	Second grade	Fourth grade
Large animal	.55	.57	.71†
Small animal	.22*	.45	.63
Rock	.55	.39	.88**
Metal	.45	.48	.87**
Kind Identity	.50	.62	.71†

Note. Binomial test results (two-tailed).

Experiment 3

Results from Experiment 2 clearly suggested a developmental shift in children's endorsement of distributed views of essence. However, on the basis of that study alone, it was unclear exactly why younger children were at chance levels of responding. To address this question in Experiment 3, we employed a different but related measure to probe children's notions about essence. In this study, children were presented with two different kinds of objects that appeared the same on the outside. For example, children saw a picture of two lions that looked identical. However, they were told that one of the animals was a real lion, whereas the other was actually a tiger in a very good lion costume. Children were told that in order to figure out which was the real lion and which was the tiger, scientists looked at tiny pieces taken from the insides of the animals (see studies by Lizotte & Gelman, reported in Gelman, 2003, for a similar task in which children identify "insides" as vital to identifying the proper category). Unlike Experiment 2, however, we specified where the pieces were taken from—for example, from the middle of the animal and from the leg. This task was designed such that a distributed response would be to say that both pieces would tell you the same, whereas a localist response would be to say that a piece from one location might tell you better than a piece from another location. This task was in many ways superior to the task used in Experiment 2 because it eliminated any ambiguity about where the tiny pieces were taken from or how many their were. Moreover, this task better focused children's attention to "unseen," internal differences between the kinds, because the outward appearances of the objects were identical.

In this experiment, we also asked about artifacts to test the degree to which notions of distributed microstructure might be specific to animals and substances. Children saw two artifacts that looked identical on the outside, yet were different on one internal dimension (e.g., a pen and a mechanical pencil). For artifacts, a single functional component may indeed be the critical feature needed for categorization. Most artifacts are constructed of similar materials (e.g., plastics, various metals or alloys, wood, etc.), and rarely is it possible to distinguish an artifact solely on the basis of its *distributed* internal properties. Rather, these identifying markers of kind tend to be single functional units that in some way define or directly support that artifact's unique function. Thus, we predicted that children might have different intuitions about artifacts than animals and substances. For these items, all age groups should report that there is only one part (such as lead or ink) that can identify the object's category.

Method

Participants. A new group of 60 children participated in this study, including 20 kindergarteners (*M* age = 6.5), 20 second graders (*M* age = 8.5), and 20 fourth graders (*M* age = 10.5). Altogether there were 32 boys and 28 girls, roughly evenly distributed across grade. As in the previous study, participants were from middle- and upper-middle-class backgrounds and were recruited at public and private elementary schools. Ethnicity breakdowns were as follows: Caucasian ($n = 56$), Hispanic ($n = 1$), and African American ($n = 3$).

Stimulus materials and procedure. Participants were first shown a picture of two objects that appeared the same on the outside (see Figure 2). The experimenter said:

> Scientists find two animals. They know that one animal is a real lion and they know that the other animal is actually a tiger in a very good lion costume. Someone has played a trick and they have dressed up a tiger in a special skin-tight costume that makes it look just like a lion. The scientists cannot tell which is the real lion just by looking at them because they both look exactly the same on the outside. In order to figure it out, the scientists take really tiny pieces from the insides of the animals. Each piece is really, really, tiny. It is about the size of a pea. They will use all their tools and technology to look at the tiny pieces and they can see everything that is inside each piece. The scientists took a tiny piece from here in each of the animals (the middle), and the scientists took a tiny piece from here in each of the animals (the leg).

Participants were then asked:

> Which piece do you think will tell them the most about which is the real lion and which is the tiger? The piece from the middle, the piece from the leg, or will they both tell them the same?

For half of the participants, the middle piece was discussed first and for the other half of the participants, the leg piece was discussed first. This procedure was repeated for five additional pairs of items that consisted of one additional animal item (zebra/horse), two substance items (gold/coal and cement/wood), and two artifacts (pen/pencil and battery-operated watch/wind-up watch). The protocol was identical for each set of items, except for as follows: For substance items, the tiny pieces were taken either from the middle of the object or from a location that was off center. For artifact items, the tiny pieces were taken either from the middle of the object or from a nonfunctional location (the back of the pen or the band of the watch). Materials were presented in one of the four different randomized orders that varied the sequence in which each item was presented as well as which location (i.e., middle or other) was presented first.

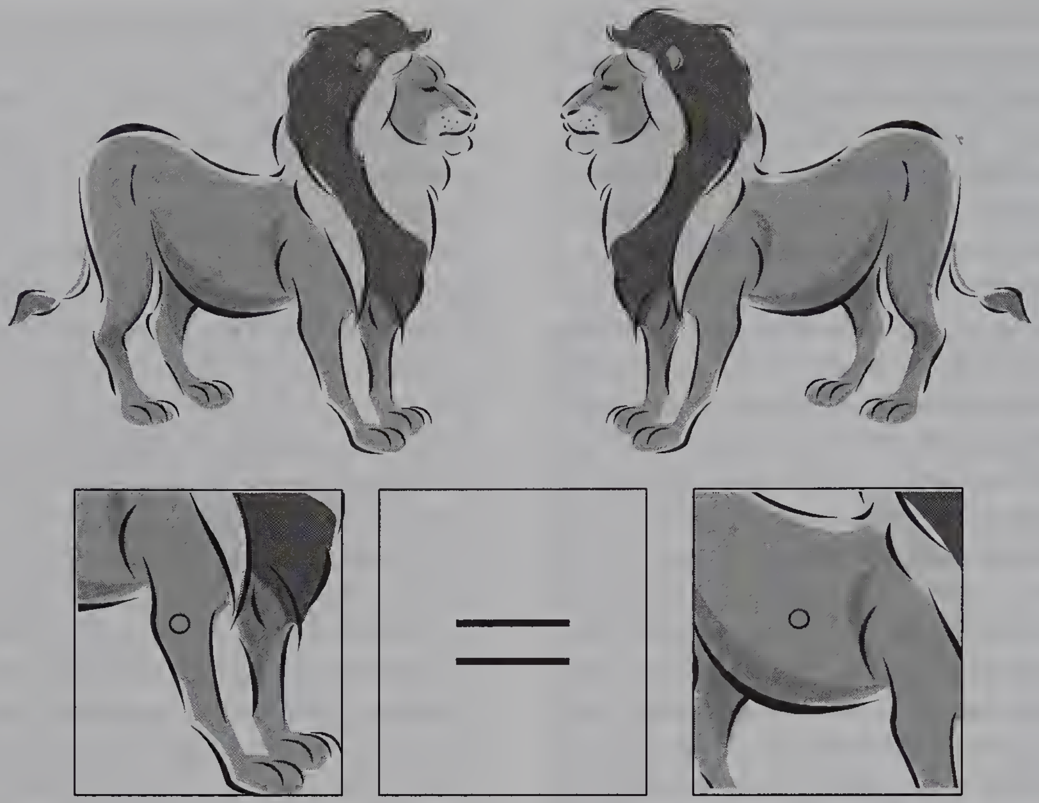

Figure 2. Sample pictures used in Experiment 3.

Results

Children's responses were classified as either *center* (e.g., "only the piece from the middle can identify the object") *other* (e.g., "only the piece from the inside of the leg can identify the object") or *both* (e.g., "both locations can identify the object"). The *center* and *other* options reflected a localist view of essence, whereas the *both* option reflected a distributed view.

The results from Experiment 3 are reported in Table 3. Consistent with the previous study, we found significant differences in the pattern of responses between age groups. We compared each of the grade levels using a Fisher's exact test and found significant differences between grades for the "gold/coal" ($p < .05$) and "cement/wood" ($p < .01$) items, and the same trend was present for the "lion/tiger" item ($p = .12$). There were no differences between grades for either of the artifact items (both $p > .24$). We then looked at each age group separately. Fourth graders were significantly more likely to say that pieces from *both* internal locations could identify "gold/coal," and "cement/wood" items ($p < .05$), and the "lion/tiger" item ($p = .055$) via binomial tests (two-tailed). As predicted, however, fourth graders were significantly more likely to say that pieces from "the center" could identify the "pen/pencil" and "watch" items ($p < .01$) via binomial tests. Additionally, because we predicted differences between natural kinds and artifacts, we

Table 3
Proportion of Children in Each Age Group Choosing Center, Other, *and* Both *Options in Experiment 3*

	Kindergarten			Second grade			Fourth grade		
Item	Center	Other	Both	Center	Other	Both	Center	Other	Both
Lion	.55*	.15	.30	.25	.30	.45	.40	.05	.55†
Zebra	.50	.28	.22	.30	.25	.45	.35	.15	.50

$^{\dagger}p < .1$. $^{*}p < .05$. $^{**}p < .01$.

compared fourth graders' pattern of responding to each of the natural kinds items against the pattern of response to the two artifact items. Each of these comparisons was statistically significant via Fisher's exact tests (all $ps < .001$).

Second graders' pattern of response did not differ from chance for the natural kind items (all $p > .18$). However, similar to fourth graders, the second graders were significantly more likely to say that pieces from *the center* could identify the "pen/pencil" and "watch" items ($ps < .01$) via binomial tests. We then compared their pattern of response to each of the natural kind items against the artifact items via Fisher's exact tests. Each of these comparisons was statistically significant (all $ps < .001$).

In contrast, kindergarteners showed a very different pattern of response, as they tended to report that only the piece from *the center* could identify the natural kind objects. They were more likely to agree with the center option for the "gold/coal," and "cement/wood" items ($p < .01$), the "lion/tiger" item ($p = .055$), as well as the "watch" item ($p < .01$) via binomial tests (two-tailed). Unlike older children, kindergarteners' pattern of response to each of the natural kind items was not statistically different from the two artifact items, as they tended to endorse the "center" location option throughout.

Discussion

Experiment 3 found a developmental shift in how children think about the physical nature of essential features. Consistent with the previous experiment, fourth graders endorsed a distributed view of essence for animals and substances. In contrast, kindergarteners reported that for both animals and substances, the essence was localized to one specific region. And, second graders appeared to reflect a transition between these two understandings, as their responses were split between distributed and localized responses.

These data also helped resolve unanswered questions from the previous study. A concern from Experiment 2 was whether younger children really do show a preference for the localist view. Indeed, kindergarteners were significantly more likely to report that a "center" location would identify the objects for several of our items, even when given the option of another single, internal location. This pattern preliminarily suggests that kindergarteners actually appear to hold a rather specific belief about the physical nature of essence—namely, that it is located in the center of the object, for both animals and substances.

Data from the artifact items suggest that by at least fourth grade and possibly earlier, children make a sharp distinction between natural kinds and artifacts in terms of how they think essences are physically realized. For natural kinds, older children appreciate that essential features are distributed throughout the entity. However, for artifacts they recognize that there may be only one single location that correctly identifies the object. Kindergarteners, however, did not show this distinction, as they tended to favor a localist view throughout.

Finally, across all items, we tended to find greater agreement with the distributed view for substances than for animals. This result again parallels the results found in both Experiments 1 and 2. The appearance of such a pattern across three experiments is consistent with the interpretation that distributed beliefs about homogenous substances tend to emerge earlier than do distributed beliefs about animals and that such intuitions may, in fact, be used to buttress a distributed understanding of animals.

General Discussion

Children, as young as 6 years old, do not seem to be agnostic about the physical nature of essence. However, these younger children, contrary to adults, favor the view that essences are localized to the center of objects—not only for animals but for minerals as well. Around second grade, children begin shift away from this localist view to recognize that for minerals at least, essential features are distributed throughout. By fourth grade, children, like adults, recognize that for both minerals and animals, essential features are distributed—a view which they apply to natural kinds, but not to artifacts.

This shift from localist to distributed accounts is a developmental pattern that is distinct from what might be predicted by a "barest placeholder" notion of essence. We argue that instead, it may be incoherent to have a notion of essential features without some sense of how those features are physically instantiated. Thus, children and adults tend to constrain their inferences about essential features by making some rudimentary assumptions about where those features may be located: Initially, children seem to think of the essence as a single, localized thing, buried somewhere within the center. However, over time, this view is replaced with the notion that essential features are located throughout.

Not only do these results suggest that children may go beyond the barest placeholder notion of essence, but they also potentially speak to alternative accounts in the literature, which have argued that "blind-faith" essentialism based on barest placeholder notions alone may be implausible. For example, it has been suggested that children represent a few causal laws that link innards and heredity to phenomenal properties and that these laws masquerade as essentialist-like biases (Strevens, 2000). Along with others, we do not agree that such alternatives negate essentialism (see Ahn et al., 2001). Rather, we suggest that the results of the present studies point toward the idea that there is a drive to contextualize essentialism in terms of a more elaborate framework of causal assumptions—a framework that, for example, makes assumptions about how essences are physically instantiated. The critical modification here, however, is that this set of causal assumptions is far different from a detailed mechanistic understanding. It instead seems to consist of a very general sense of how and where causal features are located.

Indeed, the shift to a distributed view seems to occur without the benefit of detailed biological models or adult-like understandings of biology. Only one child in both studies ever mentioned DNA, and traditionally the concept of DNA is not introduced until sixth or seventh grade, at least 2 years older than children in our studies. Thus, even though a distributed view and knowledge about DNA make similar predictions about the location of identifying features (i.e., they can be found anywhere inside an entity), convictions about distributed essence seem to occur at a level of understanding far above that of concrete mechanism. The convictions instead seem to consist of a general sense of a causal pattern and its association with natural kinds. The presence of distributed reasoning in the absence of concrete theories about actual physical structures is additional support for the idea that children go beyond the barest placeholder notion of essence.

One potential limitation to these findings, however, concerns different sizes of microstructure. It is the case that the level of analysis suggested by our stimuli (e.g., pea-sized pieces) is larger than the level at which DNA is normally envisioned. And, for some adults, this may indeed result in different forms of reasoning. For children, however, we doubt that this difference was a factor. Moreover, attempts to realistically describe the appropriate microscopic scale would have not been feasible and well beyond the scope of this set of experiments. Thus, although we do not feel that this limitation prevents interpretation of these studies, it is an interesting question for future work as to how reasoning might vary as a function of the scale of the internal sample.

How might the shift from a localist to a distributed view of essence occur? One possible way may be through analogies to minerals, which seem to be understood as distributed somewhat earlier than living kinds. Experiment 1 found that adults were more likely to endorse the distributed account for minerals than they were for animals. Similarly, Experiments 2 and 3 found that the older children in our samples tended to endorse a distributed account for minerals more often than for animals. This pattern suggests a tendency to think that minerals are more likely to have distributed essential features than animals. We speculate that this contrast might be due to a number of factors. For example, real-world experience with substances such as rocks would reveal that their internal composition is homogenous. It may be that this type of real-world observation directly aided the distributed view in our tasks—for instance, leading children to respond that the scientists could take a piece from "anywhere" on the inside and still be able to identify the object's category. In turn, a distributed view of animals may occur through analogy to substances. Children may link knowledge about homogeneous distributed structures in substances to unseen distributed structures in animals. At the same time, though the data support the emergence of distributed reasoning for substances before animals, the hypothesis that real-world knowledge about substances actually "launches" later notions about living kinds needs to be confirmed in more focused experimental studies.

Moreover, this explanation does not address why younger children may hold a localized view of essence in the first place. A second, though not mutually exclusive, mechanism may be that the shift from localist to distributed accounts represents a more fundamental change in assumptions about the causal connection between internal causes and category membership. Previous work suggests that adults are often biased to prefer properties as central to categories when they are the single initial element in a causal chain (e.g., Ahn, 1999). It may be that younger children confuse a theoretical preference for a single, initiating cause with the physical existence of centrally located structures. This would be consistent with the finding that although young children insist that there is an identifying feature located in the center of objects, they never specify a particular internal part. It is also consistent with work showing that *what* children actually think the essence of an animal is, may change as a function of that child's particular culture (Waxman, Medin, & Ross, 2007). Moreover, in the case of substances, where young children express the same beliefs about a localized identifying feature, it is even less clear what actual physical structures could guide their intuitions, as there are none. It may be that the idea of a single initiating causal element is so compelling that it overrides considerable experiences with homogeneous substances suggesting otherwise.

We now return to the differences in adults' endorsement of the distributed statements between animals and substances. At the outset, we would have no reason to expect that adults should hold different views about animals and substances. However, we suggested that one explanation for adults' willingness to endorse Distributed views more often for minerals than for animals might be because more developmentally primitive ways of viewing these structures (i.e., localist notions) compete with the explicit knowledge that such features are distributed. To illustrate this point, consider the difficulty of reconciling Fact 1—that there is a single causal element, DNA, that causes biological kinds to be different—with Fact 2—that this same element is equally distributed around the body (represented in all nucleated cells). Although we speculate that most Western adults who have taken at least high school-level biology can confidently produce both of these facts, when it comes to explaining how DNA is then responsible for complex, synchronized developmental changes like growth or puberty, we speculate that most people's explanations will tend to fall flat—or more likely, revert to some sort of localist notion (e.g., that there is one special factor that oversees the process). Of course, this speculation requires empirical investigation, but examples such as this one raise important questions about what happens when even adult folk-biological models have to confront the true complexity of the biological world. We argue that people's lay models may have to be at least "a little localist" at times, simply because often the phenomena in question are so complex that they must be reduced to single-cause frameworks. Similarly, younger children, for reasons that are either specific to their particular theories of biology or constraints on their processing, may also be, in a sense, "required" to take a localist view of essential properties, merely because it represents a simpler causal story.

An additional mechanism that may promote these different views of essence could be some sort of instruction that is particular to a given culture. Would we see the same developmental patterns 150 years ago, before Mendel published his work on genetics—or even 200 years ago, before Brown observed the motion of microscopic particles? Or, would we expect the same patterns cross-culturally, in remote groups that might not be familiar with concepts such as DNA or atoms? Here, it is difficult to speculate, as the answers to these questions largely depend on how one believes children acquire notions of a distributed essence in the first place. On the one hand, if children develop such beliefs either through analogies to substances or a more profound change in their assumptions about underling cause, then we would expect the same types of patterns to occur, regardless of time or place. There is some support for this position, as ideas about atomistic or inherent, unseen causes far predate modern science and are culturally pervasive (Sober, 1994).

On the other hand, it may be that notions of a distributed microstructure reflect, or are in some way aided by our modern, Western scientific view. For example, work by Waxman et al. (2007) finds culturally specific intuitions about the nature of biological causes in children. They presented children from several different cultures with versions of the adoption paradigm in which children were told about a baby pig that was adopted and raised solely by other cows. Children were then asked about many of the pig's properties such as what sorts of things would be "pig like" and what sorts of things would be "cow like." Across all cultures, they found evidence for a strong biological component to children's understanding of property inheritance. Native American children, however, seem to have more firm commitments about the biological mechanism underlying the transmission of properties from parent to offspring. They often reported that the blood was essential, a belief that is widely shared among adults in this culture as well. The authors concluded that "children may be more likely to consider biological than nonbiological processes as candidate essences, and that in identifying candidate biological processes, they are sensitive to community-wide discourse" (p. 306). Thus, it is certainly plausible that children's notions of distributed essence are in some way shaped or buttressed by our modern scientific understanding and language.

In sum, we propose that even quite young children do not simply believe in a completely unspecified, barest placeholder notion of essence. In other words, they are not "blind-faith essentialists." Instead, they seem to embed essentialism into a more complex causal framework that takes into account the way in which essences may be physically instantiated. For natural kinds, children have some notions about the physical nature of essential features and will constrain their decisions about identifying features accordingly. At the same time, children may well be misguided early on, favoring a localized view of identifying features because it fits with a seemingly simpler causal story.

The University of North Carolina – Chapel Hill

Disruptive behavior, including aggression, defiance, and temper tantrums, typically peaks in early toddlerhood and decreases by school entry; however, some children do not show this normative decline. The current study examined disruptive behavior in 318 boys and girls at 2, 4, and 5 years of age and frustration reactivity, physiological regulation, and maternal behavior in the laboratory at 2 years of age. A latent profile analysis resulted in 4 longitudinal profiles of disruptive behavior, which were differentiated by interactions between reactivity, regulation, and maternal behavior. A high profile was associated with high reactivity combined with high maternal control or low regulation combined with low maternal control. Results are discussed from a developmental psychopathology perspective.

Disruptive behaviors, such as aggression, defiance, and temper tantrums, are some of the most common problems seen in children (Beauchaine, Strassberg, Kees, & Drabick, 2002). Furthermore, chronic disruptive behavior problems are resistant to treatment and result in significant costs to society over time (Shaw et al., 1998). Given the negative effects and stability of disruptive behavior, it is important to identify its antecedents in order to develop useful early intervention and prevention programs. Typically, children's early social development includes a moderate level of disruptive behavior, which normatively desists (declines) across early childhood as early exposure to conflict helps children attain prosocial strategies (Owens & Shaw, 2003; Tremblay, 2000). However, some children retain their disruptive behavior across childhood, which often leads to antisocial behavior in adolescence and adulthood (Broidy et al., 2003). Understanding the precursors of persistent problem behavior may inform prevention efforts by elucidating the skills important to developing prosocial behavior and the risk factors that thwart these positive trajectories.

Consistent with a developmental psychopathology framework, theories of externalizing behavior suggest individual differences in developmental patterns of disruptive behavior. For example, past work has suggested two patterns of externalizing behavior, a high persistent pattern and a normative pattern (Moffitt, 1993). Additional research has demonstrated more than two longitudinal patterns of aggressive and nonaggressive externalizing behavior problems (Maughan, Pickles, Rowe, Costello, & Angold, 2000). Although typically defined a priori, these patterns can be empirically estimated using new statistical techniques, such as semiparametric mixture modeling (Muthén, 2004; D. S. Nagin & Tremblay, 2005). Studies using these techniques reveal empirical support for several patterns of disruptive behavior across early childhood (Hill, Degnan, Calkins, & Keane, 2006; National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2004; Shaw, Gilliom, Ingoldsby, & Nagin, 2003; Shaw, Lacourse, & Nagin, 2005). In addition, examining multiple longitudinal patterns of behavior,

rather than a single pattern or behavior at a single time point, will better represent the complexity of developmental pathways compared with more traditional approaches (Sroufe & Rutter, 1984).

The existence of multiple patterns of disruptive behavior has been supported; however, the array of factors that might distinguish these early chronic trajectories from more normative trajectories is less clear. Child and maternal factors, such as temperamental reactivity, emotion regulation, and maternal control, have been posited to influence children's ability to effectively control their emotions and learn socially appropriate behavior (Calkins, 1994; Calkins & Degnan, 2006). Previous research examined a few of these factors as direct predictors (Hill et al., 2006; NICHD Early Child Care Research Network, 2004; Shaw et al., 2005), and one study examined interactions of these factors in relation to longitudinal patterns of disruptive behavior in early childhood (see Shaw et al., 2003). However, from a developmental psychopathological perspective, further exploration into the joint effects of temperament and maternal behavior on longitudinal patterns of externalizing behavior problems is essential to fully inform prevention efforts. The concepts of multifinality and equifinality imply that both child and maternal factors may relate to specific levels of disruptive behavior problems in multiple ways (Cicchetti & Rogosch, 1996). Thus, the present study examined frustration reactivity, physiological regulation, and maternal controlling behavior in toddlerhood as joint predictors of the probability of membership in longitudinal profiles of disruptive behavior across early childhood.

Predictors of Longitudinal Profiles of Disruptive Behavior

One constellation of factors suggested to contribute to the maintenance of disruptive behavior is temperament, which includes reactivity to the environment and regulation of that reactivity (Cole, Martin, & Dennis, 2004). The stable and enduring aspect of temperament is thought to be an individual's level of emotional and motor reactivity during an emotionally challenging context, which is influenced by regulatory systems over time (Rothbart & Bates, 2006; Rothbart, Derryberry, & Hershey, 2000). In fact, observed measures of emotional reactivity during emotion-eliciting situations are moderately stable (Calkins, 2002; Stifter & Fox, 2000) and related to important behavioral outcomes (for a detailed review, see Rothbart & Bates, 2006). Whereas reactivity to novelty has been linked to internalizing behaviors (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001), frustration reactivity has been linked to externalizing behaviors in toddlerhood and early childhood (Calkins, 2002; Hubbard et al., 2002). For instance, children who are highly reactive to frustration may act aggressively when provoked or aggravated because of their tendency to perceive these provocations as hostile (Vitaro, Brendgen, & Tremblay, 2002). In general, negative difficult temperamental components are associated with externalizing behavior problems (Rothbart & Bates, 2006). However, research exploring the effects of frustration reactivity on longitudinal patterns of problem behavior across early childhood is limited (see Shaw et al., 2005, for an exception).

Children's frustration reactivity is thought to be stable, but it is also influenced by regulatory systems over time (Rothbart & Bates, 2006; Rothbart et al., 2000). Thus, in addition to frustration reactivity, emotion regulation is also suggested to influence disruptive behavior. Whereas frustration reactivity is the emotional excitation of an individual, emotion regulation is the biological or behavioral process that alters that reactivity (Rothbart, Ahadi, & Evans, 2000). Through both physiological and behavioral factors, children first develop strategies to regulate arousal, which later develop into a formal repertoire of skills used to actively regulate emotions and behavior in a variety of contexts (Calkins, 1994; Calkins & Degnan, 2006). These skills lead to positive social skills and a decline in disruptive behavior over time (Denham & Burton, 1996). Emotion regulation is typically measured as behavior or physiology during situations that have presumed regulatory demands and elicit specific regulatory behaviors (Cole et al., 2004). A physiological construct frequently linked to emotion regulation is vagal tone (VT). When there are external demands, the autonomic nervous system supports the arousal of the sympathetic system by withdrawing the parasympathetic (vagal) input to the heart and other organs in order to promote fight/flight behaviors (Porges, 1991; Porges, Doussard-Roosevelt, & Maiti, 1994). Thus, under stress or challenge, respiratory sinus arrhythmia (RSA, an estimate of VT) is expected to decrease from baseline (vagal withdrawal; Porges et al., 1994), and this decrease is related to lower frustration reactivity, the use of emotion regulation skills (Calkins, 1997; Calkins, Dedmon, Gill, Lomax, & Johnson, 2002), and fewer behavior problems (Calkins & Dedmon, 2000; Eisenberg, Fabes, & Murphy, 1996).

Children's levels of frustration reactivity and physiological regulation have been directly related to externalizing behavior problems at specific time periods throughout childhood, but the longitudinal implications of early reactivity–regulation profiles are unknown. In addition, temperamental reactivity and emotion regulation are hypothesized to interact in relation to children's social adjustment (Calkins & Degnan, 2006; Rothbart & Bates, 2006; Sanson, Hemphill, & Smart, 2004). Undoubtedly, when children are able to regulate their frustration reactivity, they are better able to interact in a positive social manner. However, if children have limited regulatory skills and are prone to frustration, they are likely to develop maladaptive social behavior. Studies examining these types of interactive effects found that a combination of higher frustration reactivity and lower regulation skills predicts greater defiance (Stifter, Spinrad, & Braungart-Rieker, 1999), lower social competence (Belsky, Friedman, & Hsieh, 2001; Calkins, Gill, Johnson, & Smith, 1999), and greater externalizing behavior problems (Diener & Kim, 2004; Eisenberg et al., 2000). Also, an examination of observed and physiological measures of reactivity and regulation found that observed distress at 2 years of age was negatively related to 4-year positive social adjustment, but only for those children with lower physiological regulation (Calkins & Degnan, 2005). This work suggests that children's frustration reactivity and emotion regulation interact to predict disruptive behavior problems; however, few studies have explored these interactions in relation to longitudinal patterns of behavior. From a developmental psychopathology viewpoint, examining measures of reactivity and regulation from multiple levels of analysis as joint influences on longitudinal pathways of behavior problems would support the value of these skills for the development of positive social behavior (Kuperminc & Brookmeyer, 2006). Therefore, the current study examined the joint effects of observed frustration reactivity and physiological regulation in toddlerhood in relation to longitudinal patterns of disruptive behavior in early childhood.

Another factor that influences children's levels of frustration reactivity, emotion regulation, and socially appropriate behavior is maternal behavior. From birth, caregivers assist infants with general state regulation by providing basic necessities (e.g., food and clothing); however, during the transition to toddlerhood, this assistance evolves into more complex social interactions in which children learn to manage their own distress and behavior. The development of these self-management abilities is expected to occur with the support of a positive mother – child relationship (Calkins, 1994). In contrast, children's aggression, noncompliance, or broader externalizing problems are associated with controlling, rejecting, or harsh parenting behavior (Campbell, Pierce, Moore, Marakovitz, & Newby, 1996; Rubin, Hastings, Chen, Stewart, & McNichol, 1998; Shaw et al., 1998).

Maternal behaviors, such as control or rejection, may also interact with children's frustration reactivity and emotion regulation in relation to disruptive behavior problems (Calkins & Degnan, 2006; Rothbart & Bates, 2006). For instance, maternal behavior may enhance or undermine the development of important regulatory skills, which reactive children would have difficulty acquiring otherwise (Braungart & Stifter, 1991; Calkins, 2002; Calkins, Smith, Gill, & Johnson, 1998). Specifically, mothers who are sensitive and responsive may help children who have high frustration reactivity and regulatory difficulties develop appropriate social behavior. In contrast, mothers who are intrusive or hostile may exacerbate their children's frustration reactivity and poor regulatory skills, leading to greater disruptive behavior problems (Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002; Rubin, Burgess, Dwyer, & Hastings, 2003). Supporting this notion, research examining the joint effects of maternal behavior and temperament reveals that children's frustration reactivity typically predicts externalizing outcomes when mothers are high on control or low on positivity (Calkins, 2002; Paterson & Sanson, 1999; Rubin et al., 2003). However, one study found that maternal control had a positive impact on children's frustration reactivity (Bates, Pettit, Dodge, & Ridge, 1998), suggesting that the same level of maternal control may not operate the same way in all contexts or with all children. In some instances (e.g., when danger is present; Bates et al., 1998), maternal control may help dampen children's frustration reactivity and limit the display of disruptive behavior. However, in other situations (e.g., free play; Calkins, 2002), maternal control may exacerbate a negative temperament and increase disruptive behavior. In addition, maternal control may lead to disruptive behavior when children are not prone to frustration but have strong approach tendencies. Parents of this type of child may attempt to inhibit the approach behavior, frustrate the child, and increase the likelihood of disruptive behavior (Derryberry & Reed, 1994). Overall, maternal controlling behavior may have different implications for child externalizing outcomes depending on the child's individual level of frustration reactivity and regulatory capabilities. Therefore, the current study examined the joint effects of maternal control, child observed frustration reactivity, and child physiological regulation in toddlerhood in relation to longitudinal patterns of disruptive behavior in early childhood.

Goals and Hypotheses

Consistent with the goal of developmental psychopathology, this study aimed to examine multiple longitudinal patterns of disruptive behavior while investigating the joint effects of both child and maternal factors on these multiple patterns of development. The primary goal of this study was to use a semiparametric group-based approach to examine latent profiles of disruptive behavior from 2 to 5 years of age. Multiple longitudinal patterns of disruptive behavior across childhood were expected due to individual differences in the initial propensity for externalizing behavior problems and the development of socially appropriate behavior over time (Moffitt, 1993; Owens & Shaw, 2003). Similar to those found in previous research on early childhood (e.g., Hill et al., 2006; Shaw et al., 2003), four profiles of disruptive behavior were hypothesized to emerge: a high profile; a high, declining profile; a moderate, declining profile; and a low profile.

The second goal of this study was to examine the joint effects of observed child frustration reactivity, physiological emotion regulation, and observed maternal controlling behavior in toddlerhood on the probability of membership in the profiles. Toddlers prone to high frustration reactivity were hypothesized to exhibit high levels of disruptive behavior; however, physiological emotion regulation was posited to protect children from maintaining these behavior problems across early childhood. In addition, the level of maternal control was expected to be positively related to profiles with greater disruptive behavior problems in general, but especially when children displayed higher rates of frustration reactivity and lower physiological regulation. Although these factors (frustration reactivity, physiological regulation, and maternal control) have been directly related to disruptive behavior problems in previous work, the present study examined how they might interact to differentiate multiple profiles of disruptive behavior over early childhood. Although this approach was somewhat exploratory, specific interaction effects were expected to emerge. Specifically, high levels of frustration reactivity, lower levels of physiological regulation, and higher maternal control were hypothesized to increase the likelihood of membership in the high disruptive behavior profile. In contrast, the probability of membership in the high, declining profile was expected to be related to a combination of higher levels of both frustration reactivity and physiological regulation supported by lower levels of maternal control. The probability of membership in the moderate, declining and low profiles was expected to be related to lower levels of frustration reactivity, higher levels of physiological emotion regulation, and lower levels of maternal control. However, a higher probability of membership in the moderate, declining profile was expected to be related to slightly more frustration reactivity than the probability of membership in the low profile. In summary, child frustration reactivity, physiological emotion regulation, and maternal control were expected to collectively differentiate the probability of membership in the disruptive behavior profiles.

Method

Participants

Participants for the current study were part of a longitudinal study of four hundred and forty-seven 2-year-old children (215 boys and 232 girls) obtained from three cohorts. Sixty-seven percent were European American, 27% were African American, 4% were biracial, and 2% were Hispanic. At age 2, the children were primarily from intact families (77%) who were economically diverse with Hollingshead (1975) scores ranging from 14 (unskilled laborers/menial service workers) to 66 (major business professionals), with an average score of 39.56 (medium business professionals). Parental education levels ranged from some high school (3% mothers and 6% fathers) to advanced degrees (12% mothers and 11% fathers), and over 30% of mothers and fathers had completed college.

Recruitment

The goal for recruitment was to obtain a representative community sample of children, some of whom were at risk for developing future externalizing behavior problems. Thus, all cohorts were recruited through child day care centers, the County Health Department, and the local Women, Infants, and Children program. The sample was screened by gender to obtain equal numbers of males and females. In addition, recruitment was targeted to all areas of the county to obtain a sample representative of the surrounding area in terms of race and socioeconomic status (SES).

Potential participants for Cohorts 1 and 2 ($n = 307$) were recruited at 2 years of age (Cohort 1: 1994 – 1996 and Cohort 2: 2000 – 2001) and screened using mother report on the Child Behavior Checklist (CBCL 2 – 3; Achenbach, 1992). Children with an externalizing T score of 60 or above were selected to be in the *externalizing risk* group ($n = 143$). Those with both externalizing and internalizing T scores below 60 were selected to be in the *low-risk* group. Cohort 3 was initially recruited when infants were 6 months of age (in 1998) for their level of frustration based on laboratory observation and parent report (see Calkins et al., 2002, for more information). This cohort was followed from 6 months of age through the infancy and toddler period, and children whose mothers completed the CBCL at 2 years of age were included in the current study (*n* = 140). Based on the criteria described earlier, 21 children from this cohort were placed in the externalizing risk group. Cohort 3 had a significantly lower average 2-year externalizing *T* score (*M* = 50.36) compared to Cohorts 1 and 2 (*M* = 54.49), *t*(445) = −4.32, *p* = .00. Of the entire sample (*N* = 447), 164 children met criteria for the externalizing risk group. There were no significant differences between any cohorts with regard to gender, $\chi^2(2, N = 447) = 0.63, p = .73$; race, $\chi^2(2, N = 447) = 1.13, p = .57$; or 2-year SES, *F*(2, 444) = 0.53, *p* = .59.

Missing Data

Of the 447 participants originally selected at 2 years of age from maternal report on the CBCL, 6 were dropped because they did not participate in any 2-year laboratory data collection. At 4 years of age, 399 families participated. Families missing at 4 years of age included 20 who could not be located, 10 who moved out of the area, 9 who declined participation, and 9 who did not respond to phone and letter requests to participate. There were no significant differences between families who did and did not participate at 4 years of age in terms of gender, $\chi^2(1, N = 447) = 3.27, p = .07$; race, $\chi^2(1, N = 447) = 0.70, p = .40$; 2-year SES, *t*(424) = 0.81, *p* = .42; or 2-year externalizing *T* score, *t*(445) = −0.36, *p* = .72. At 5 years of age, 365 families participated including 4 who did not participate in the 4-year assessment. Families missing at 5 years of age included 12 who could not be located, 10 who moved out of the area, 13 who declined participation, and 3 who did not respond to phone and letter requests to participate. Again, there were no significant differences between families who did and did not participate at 5 years in terms of gender, $\chi^2(1, N = 447) = 0.76, p = .38$; race, $\chi^2(1, N = 447) = 0.17, p = .68$; and 2-year externalizing *T* score, *t*(445) = −1.73, *p* = .09. There was a trend for a difference between the families who did or did not participate at 5 years in terms of 2-year SES, *t*(424) = 1.93, *p* = .06, such that families with lower SES were not as likely to participate, although this effect size was minimal (*d* = 0.22).

Procedures

Two-Year Assessment

Mothers brought their children to the laboratory and were videotaped during several episodes designed to elicit frustration reactivity and mother–child interaction. All episodes were videotaped for later coding. If the child became highly distressed (i.e., cried hard for more than 30 s), the episodes were ended early. In addition, mothers were asked to complete multiple questionnaires including the CBCL 2–3 (Achenbach, 1992) and a demographic measure. At the end of the laboratory visit, mothers were compensated for their time and children were given a small prize for their participation.

RSA assessment. At the beginning of the 2-year laboratory visit, an experimenter placed three disposable, pediatric electrodes in an inverted triangle pattern on the child's chest. The electrodes were connected to a preamplifier, and the output from the preamplifier was transmitted to a vagal tone monitor (VTM-I; Delta Biometrics, Bethesda, MD) for R-wave detection. The vagal tone monitor displayed heart rate throughout the baseline, toy/cookie in box, and teaching episodes, and every 30 s, it computed and displayed RSA values. A data file containing the interbeat intervals (IBIs) for the entire period of heart rate collection was saved on a laptop computer for later artifact editing (e.g., resulting from child movement) and analysis. For the current study, only RSA measures during the baseline and first frustration (toy/cookie in box) episodes were used.

For the baseline episode, the child watched a 5-min segment of the videotape "Spot," a story about a puppy that explores its neighborhood. Although this episode was not a true baseline, as the child's attention was engaged, it was sufficient to gain a measure of RSA while the child was sitting quietly and showing neutral affect. Given these children were 2 years of age, such a stimulus was necessary in order to limit movement artifact in the heart rate data. Following the baseline episode was the first frustration episode (toy/cookie in box) during which the children were asked whether they wanted a snack or to play with an exciting toy. If the child was asked to play with a toy, they were permitted to play with the toy for 1 min. Then, the experimenter placed the snack or toy in a clear plastic container that the child could see and touch, but was unable to open, for 2 min. Throughout this episode, the mother was nearby and was instructed to respond to the child as she normally would but to limit initiating any interaction. This task was adapted from Laboratory Temperament Assessment Battery procedures (Lab-TAB; Goldsmith & Rothbart, 1996). Next, the mother was instructed to teach the child how to complete a challenging puzzle or shape sorter for 3 (Cohort 3) or 4 (Cohorts 1 and 2) min. When the RSA assessment period was complete, the electrodes were removed from the child's chest and the child was given a snack break.

Laboratory assessment. Following the break, the second frustration task (high chair) was administered. The child was placed in a high chair, without any toys or snacks, for 5 min. Throughout this episode, the mother was seated nearby and was instructed to respond to her child as she deemed necessary. At the end of the 5 min, the child was removed from the high chair. Next, a farm or pretend town was provided and the mother was instructed to play with her child as she would at home for 4 min. Following the free play episode, the mother was instructed to get the child to clean up the toys as they would at home. This episode lasted 2 min or until all the toys were put away, whichever happened first.

Four- and 5-Year Assessments

The mothers were requested to accompany their children to the laboratory when they were 4 and 5 years of age. During these visits, mothers completed multiple questionnaires including the CBCL 4–18 (Achenbach, 1991a). For each visit, mothers were compensated for their time and children were given a small prize for their participation. For the purposes of the current study, only the CBCL data from these visits were examined.

Measures

Demographics

Mother's open response report of children's race and gender was used to measure children's race (Caucasian or minority) and gender (male or female). Mothers also reported their own and the child's father's (if he was contributing to the household) education level, marital status, and type of employment. These measures were used to construct an SES score for the 2-year laboratory visit based on the Hollingshead (1975) index. This score is derived from maternal and paternal education level and occupational strata.

Disruptive Behavior Problems

The CBCL's (Achenbach 1991a, 1992) aggression subscale was used as an index of mother-reported disruptive behavior problems at each age. When the children were 2 years of age, mothers completed the CBCL for 2- to 3-year-olds (Achenbach, 1992). When the children were 4 and 5 years of age, mothers completed the CBCL for 4- to 18-year-olds (Achenbach, 1991a). These scales are a reliable index of various externalizing and internalizing behavior problems across childhood (Achenbach, Edelbrock, & Howell, 1987). Both versions included a narrow-band *aggression* subscale, which consisted of items measuring physical aggression, anger, and general cruelty toward others. At 2 years of age, the subscale consisted of 15 items such as "defiant," "fights," and "hits others." At 4 and 5 years of age, the subscale consisted of 20 items such as "argues," "mean to others," and "physically attacks people." The mother indicated how true each item was of her child by circling 0 if *not true*, 1 if *sometimes true*, or 2 if *often true*. Although Achenbach (1991a, 1992) labeled this factor aggression, an examination of the items suggests that it is measuring a somewhat broader construct of disruptive behavior, including defiance, destructiveness, and physical aggression (Beauchaine et al., 2002). Thus, the term *disruptive behavior* will be used with regard to this measure.

Although the CBCL includes *T* scores for each subscale, for the purposes of this study, the total scores of the subscales were used in order to allow for maximum variation across the sample with a possible range from 0 to 30 for the measure at 2 years of age and 0–40 for the measures at 4 and 5 years of age. It is noted that the range and items of each scale are different because they measure identifiable and expected disruptive behaviors for either the 2- to 3- (15 items) or 4- to 18-year old (20 items) age range. On average, for this sample, the 4- and 5-year-olds' scores were lower than the 2-year-olds' scores (Table 1). In order to control for the different number of items at each age, the mean of the subscales was created by dividing the raw scores by their respective number of items, creating a possible range of scores between 0 and 2 at each age. Averages and standard deviations of the disruptive behavior total raw and mean scores are in Table 1.

Observed Frustration Reactivity

Reactivity behaviors were coded from videotapes of both frustration episodes (toy/cookie in box and high chair). Reactivity was indexed by measures of distress, including whining, pouting, fussing, crying, screaming, or tantrumming. It was coded in three ways: (a) *proportion of distress*: the amount of time (in seconds) the child was distressed divided by the total time of the episode; (b) *global negative reactivity*: coded for the entire episode on a scale from 0 (*no negative response*) to 4 (*episode ended with the child in extreme distress*); and (c) *global episode affect*: coded once for the entire episode on a scale from −3 (*highly distressed affect*), to 3 (*highly positive affect*). These measures were thought to best index a child's level of observable

Table 1
Descriptive Statistics

Measures	*N*	Minimum	Maximum	*M*	*SD*
2-year socioeconomic status	318	14.00	66.00	39.56	10.82
2-year proportion of distress	318	0.00	0.98	0.11	0.17
2-year global negative affect	318	0.00	4.00	0.75	0.85
2-year global episode affect	318	−3.00	2.00	−0.11	0.78
2-year observed reactivity score	318	−1.26	1.90	0.00	0.43
2-year baseline RSA	318	1.10	8.79	5.49	1.27
2-year frustration RSA	318	1.45	8.57	4.89	1.16
2-year physiological regulation score	318	−3.37	3.34	0.00	1.00
2-year adult-centered statements	318	6.67	41.11	20.03	5.95
2-year global strictness/punitiveness	318	1.00	4.00	2.48	0.64
2-year maternal control score	318	−2.01	2.43	0.00	0.96
2-year disruptive behavior total	318	0.00	29.00	10.04	5.68
2-year mean disruptive behavior score	318	0.00	1.93	0.67	0.38
4-year disruptive behavior total	274	0.00	28.00	8.93	5.97
4-year mean disruptive behavior score	274	0.00	1.40	0.45	0.29
5-year disruptive behavior total	252	0.00	33.00	8.73	6.84
5-year mean disruptive behavior score	252	0.00	1.65	0.44	0.34

Note. RSA = respiratory sinus arrhythmia.

frustration reactivity during episodes with presumed regulatory demands (Calkins, 1997; Stifter & Braungart, 1995). Four coders trained on 10% of the videotaped sessions and independently coded another 10% for reliability. Intercoder reliability for the proportion of distress measure was excellent, mean $r = .99, p < .00$ (range = .98 – 1.0). Reliability kappas for the ordinal codes were .83 for global negative affect and 1.0 for global episode affect. Each of the reactivity codes was correlated and averaged across episodes (average $r = .25$, $p < .00$). Descriptive statistics for each average code are reported in Table 1.

In order to compute an "observed reactivity" composite, the average codes were standardized and summed ($\alpha = .86$). This composite had a high skewness value of 1.94 and a kurtosis value of 5.53. Therefore, the composite was transformed using a square root transformation bringing the skewness value to 1.19 and the kurtosis value to 2.25. Then, the transformed composite score was centered to allow for ease of interpretation in the model. The mean and standard deviation for this final composite variable are reported in Table 1.

Physiological Emotion Regulation

Measures of children's RSA during the baseline and toy/cookie in box episodes were obtained by editing the IBI files using MXEDIT software (Delta Biometrics, Bethesda, MD.). The Porges' (U.S. Patent No. 4520944, 1985) method of analyzing the IBI data was used to calculate RSA. This method applies an algorithm to the sequential heart period (HP) data. The algorithm uses a moving 21-point polynomial to detrend periodicities in HP that are slower than RSA. Then, a band-pass filter extracts the variance in HP within the frequency band of spontaneous respiration in young children, 0.24 – 1.04 Hz. The natural log of this variance is taken and reported in units of $\ln(\text{ms})^2$. To edit the files, the data were scanned for outlier points, relative to adjacent data, and the outliers were replaced by dividing or summing them so they would be more consistent with the surrounding data. Only data files in which less than 10% of the data required editing were included in the current study. For the baseline and toy/cookie in box episodes, RSA was calculated every 30 s and averaged across epochs. Individual data were excluded if the standard deviation for an episode was over 1.0 (see MXEDIT manual; U.S. Patent No. 4520944, 1985).

Measures of RSA during the baseline and toy/cookie in box episodes were used by calculating a difference score (Calkins, 1997; Moore & Calkins, 2004) to create an index of "physiological regulation" during the frustration episode, thus taking into account the level of baseline RSA. This was done by subtracting RSA during the frustration episode from RSA during the baseline episode. Positive change scores occurred when there was a decrease from the baseline to the frustration episode, which reflects attempts to regulate emotion. Negative change scores occurred when there was an increase from the baseline to the frustration episode, which reflects a lack of physiological regulation. The RSA change score was then centered to allow for ease of interpretation in the model. Descriptive statistics for the measures of RSA during baseline and frustration episodes and the physiological regulation score are reported in Table 1.

Maternal Behavior

Maternal behavior, during the interactive episodes (teaching, free play, and cleanup), was coded with two coding systems. One system (Rubin, Booth, Rose-Krasnor, & Mills, 1995; Smith, Calkins, Keane, Anastopoulos, & Shelton, 2004) recorded the implied goal of each maternal statement: *Adult-oriented* goals included initiating a new activity (a beginning) or stopping the child's activity (a stop), as opposed to continuing or facilitating the child's own activity. The duration of episodes varied across dyad, so the sum of adult-oriented statements (beginnings and stops) was standardized for each participant by dividing the total number by the total time of the individual's episode and multiplying this value by the maximum time of the episode (teaching episode: 4 min, free play episode: 4 min, and cleanup episode: 2 min). Four coders trained on 10% of the videotaped sessions and independently coded another 10% for reliability. The average intercoder reliability for the maternal goal measures was $r = .86$, $p < .00$ (range = .81 – .88).

The second coding system (Smith et al., 2004; Winslow, Shaw, Bruns, & Kiebler, 1995) examined a global index of *strictness/punitiveness* (being too strict, demanding, or harsh relative to the child's behavior; exerting influence toward completion of the child's activity; displaying a no-nonsense attitude; and constantly guiding the child and creating a very structured environment). This was coded once for each episode on a 4-point scale, ranging from low levels of the behavior to high levels of the behavior. Four coders trained on 10% of the videotaped sessions and independently coded another 10% for reliability. The reliability kappa between each pair of coders was .71 for strictness/punitiveness.

The adult-oriented goals and the global code for strictness/punitiveness were each averaged across episodes (average $r = .44$, $p < .00$; average $\alpha = .58$). Descriptive statistics for each average code are reported in Table 1. Following Smith et al. (2004), a composite "maternal control" was created by standardizing and summing the average adult-oriented goals and global strictness/punitiveness measures ($\alpha = .76$). This composite was then centered to allow for ease of interpretation in the model. The mean and standard deviation for this maternal control measure are reported in Table 1.

Summary of Measures

The observed reactivity, physiological emotion regulation, and maternal control measures at 2 years of age and the CBCL (Achenbach, 1991a, 1992) subscales of aggression at 2, 4, and 5 years of age were examined in the present study. Of the possible 441 participants, only 318 (72%) had complete data at 2 years of age: Ninety-seven had technical difficulties with the physiological data collection, 12 could not be contacted by phone to schedule a laboratory visit but completed questionnaires through the mail, 11 had technical difficulties with the video equipment, and 3 refused to complete socioeconomic information. These families were not significantly different from the overall sample by gender, $\chi^2(1, N = 447) = 0.38$, $p = .54$; race, $\chi^2(1, N = 447) = 0.04$, $p = .85$; 2-year SES, $t(424) = 0.00$, $p = 1.0$; or 2-year externalizing T score, $t(445) = -0.21$, $p = .84$. Of these 318 participants, 274 had complete 4-year CBCL data and 252 had complete 5-year CBCL data. These families were not significantly different from those with incomplete CBCL data by gender, $\chi^2(1, N = 318) = .1.49$, $p = .22$; race, $\chi^2(1, N = 318) = 0.99$, $p = .32$; or 2-year externalizing T score, $t(316) = -1.35$, $p = .18$. However, there was a trend for those with missing data to have significantly lower 2-year SES, $t(313) = 1.95$, $p = .05$. Further analysis determined that the patterns of missing data at 4 and 5 years of age were missing completely at random (MCAR), Little's MCAR test, $\chi^2(28, N = 318) = 16.26$, $p = .96$. In addition, the present analysis used maximum likelihood estimation, which allows for missing data longitudinally and assumes the missing data across repeated measures are missing at random (Little & Rubin, 1987; Muthén & Muthén, 2006). Thus, despite missing data across time, 318 families provided data for the current study, 124 (39%) with children above the borderline clinical range on 2-year externalizing behavior and 194 (61%) with children below the borderline clinical range on 2-year externalizing behavior.

Data Analyses Goals

To investigate individual differences in longitudinal patterns of disruptive behavior, a structural equation mixture model (SEMM) was used. As a semiparametric group-based approach, SEMM allows for estimation of qualitatively different groups (i.e., classes) when group membership cannot be observed a priori (Bauer & Curran, 2004). Recent work of D. Nagin and Tremblay (1999) and Muthén (2001) showed how SEMMs can be used in testing differential longitudinal patterns of psychological phenomena. In the current study, disruptive behavior at age 2 was measured with a different form of the CBCL (age 2–3) than disruptive behavior at ages 4 and 5 (CBCL 4–18). Thus, linear growth trajectories of disruptive behavior were not estimated (e.g., D. Nagin & Tremblay, 1999) due to the possibility of change in measurement; rather, the average level of disruptive behavior at each age was estimated independently within each class (i.e., latent profile analysis [LPA]; Gibson, 1959). For this reason, classes are referred to as "longitudinal profiles" rather than trajectories. In this study, the longitudinal profiles described levels of disruptive behavior at 2, 4, and 5 years of age.

As mentioned, one benefit of using an SEMM model such as LPA is that it performs maximum likelihood estimation, which includes all longitudinal observations in a data set (Little & Rubin, 1987). This method assumes the data are missing at random and has been recently recommended by methodologists as an appropriate way to accommodate missing data (Schafer & Graham, 2002). Using this method of estimation allows the model parameters to be informed by all cases that contribute a portion of the data. As a submodel of SEMM, LPA is a multiple group structural equation model in which the group variable is unobserved. Thus, LPA assumes observed associations are explained by differences in the means of the continuous measures over latent classes (Bauer & Curran, 2004). With this framework, individual's probabilities of membership in each profile and the predictor's effects on those probabilities are estimated in the same analysis. As with a multinomial logistic regression, the analysis compares the probability of membership in all the profiles in reference to one of the profiles (e.g., 1, 2, 3 vs. 4). In addition, the statistical package used (Mplus 4.1) estimated all possible comparisons in the same analysis (i.e., tests all the other profiles as the reference profile).

Although similar to logistic regression and cluster analysis, LPA differs from past methods used to identify groups in two ways. First, LPA relies on a formal statistical model rather than an ad hoc algorithm based on decision rules (e.g., cluster analysis) and allows for flexibility in the model (Everitt & Hand, 1981). Second, the flexibility of model-based LPA allows for the possibility of uncertainty in which classes people may belong to, allowing one to predict the *probability* of membership in a group (rather than *membership* in that group per se). In other words, unlike cluster analysis, people are not forced into a group so that additional analyses can be performed to examine predictors; rather, all analyses are performed within one formal statistical model.

The function for LPA takes the general form as follows:

$$Y_{(tik)} = \mu_{(tk)} + \varepsilon_{(tik)},$$

where $\mu_{(tk)}$ is the class-specific mean for the observed variable Y at time t for class k, and $\varepsilon_{(tik)}$ are within-class individual differences from $\mu_{(tk)}$. Within each class, $\varepsilon_{(tik)}$ is assumed to be normally distributed with variance $\sigma_{(tk)}$, allowing for potential heteroscedasticity across time and classes. In this study, the Y variables are disruptive behavior scores at ages 2, 4, and 5, and the estimated class means $\mu_{(tk)}$ for these variables describe the longitudinal latent profile for each class.

In the current study, data were analyzed using Version 4.1 of Mplus (Muthén & Muthén, 2006), and models with two through six profiles were estimated. Determination of best model fit was assessed using Bayesian information criteria (BIC), where the smallest negative number indicates best fit. This index has been shown to identify the appropriate number of groups in finite mixture models (D'Unger, Land, McCall, & Nagin, 1998) and penalizes the model for the number of parameters, thus guarding against models overfitting the data. In addition, when fitting models like these, issues such as convergence are important, especially for more complex models (Hipp & Bauer, 2006), and sometimes, start values must be specified in order to reach convergence. For this case, the model was relatively simple, and random start values resulted in a converged solution. Predictors of the probabilities of membership in the above profiles were entered into the model in a hierarchical fashion. The log likelihoods of each step were compared with the prior step to determine whether the predictors significantly affected the model (McArdle, 2005). If they did not affect the model, then they were taken out to conserve power needed to detect interaction effects. Additionally, interaction effects were probed similarly to how one would test interactions in logistic regression using the guidelines of Aiken and West (1991).

Results

Descriptive Analyses

A two-way multivariate analysis of variance, with race (Caucasian vs. minority) and gender, was used to test for group differences on all outcomes variables (disruptive behavior at 2, 4, and 5 years of age). There were no significant main effects of race or gender on the outcome variables. In addition, follow-up analyses indicated that the demographic factors and their moderation effects did not significantly impact the latent class analysis above and beyond the effects of the main predictors. Thus, in subsequent analyses, gender and race are not included in the model. Correlations between 2-year SES, baseline RSA, and all outcome variables (disruptive behavior at 2, 4, and 5 years of age) revealed a single significant association. Family SES at 2 years of age was negatively related to disruptive behavior at 2 years of age ($r = -.17, p < .01$). Thus, children rated by their mothers as displaying more disruptive behavior at age 2 also had parents with lower average SES at age 2; subsequently, SES was tested in the model. Baseline RSA was not significantly related to the measures of disruptive behavior and was not controlled for in the model. Finally, correlations were computed between the predictor variables themselves (frustration reactivity, physiological regulation, and maternal control). Maternal control was not significantly associated with frustration reactivity or physiological regulation; however, frustration reactivity and physiological regulation were modestly intercorrelated, $r = .15, p = .01$.

Latent Profile Model Comparisons

Latent profile models with two through six profiles were fit to determine the optimal number of profiles to describe disruptive behavior from 2 to 5 years of age in the current sample. Model fit was assessed using the BIC, where the smallest negative number (closest to 0) indicates best fit. The BIC for the current sample was −311 for two profiles, −248 for three profiles, −238 for four profiles, −244 for five profiles, and −275 for six profiles. The four-profile model had the smallest negative BIC and therefore was selected as the best number of disruptive behavior profiles for the current sample. As a secondary test of model fit, the Lo – Mendell – Rubin likelihood ratio test was also used, which tests the significance of the −2 log likelihood difference between models with k and $k-1$ profiles (Lo, Mendell, & Rubin, 2001). Indeed, the two-profile model was significantly better than the one-profile model ($p < .001$), the three-profile model was significantly better than the two-profile model ($p < .001$), and the four-profile model was significantly better than the three-profile model ($p < .05$). However, the five-profile model was not significantly better than the four-profile model ($p = .18$), and the six-profile model was not significantly better than the five-profile model ($p = .91$). Figure 1 displays the mean levels and standard errors of disruptive behavior at each time point for each of the four profiles.

An examination of the four-profile model indicated that this model yielded unique information and had an acceptable number of members in each profile. For profiles with a small number of members, there could be danger of a local spurious solution (Hipp & Bauer, 2006). For this model, the smallest profile represented 8% of the sample and had similar residual variances to all the other profiles. In addition, the average posterior probabilities of membership ranged from .85 to .93 across the profiles, reflecting a high degree of confidence in profile assignment. In comparison, the five- and six-profile models had profiles that represented less than 8% of the sample, with posterior probabilities below .80 (the lowest was .71).

Finally, the profiles from the four-profile model were examined for outliers and normality in a post hoc analysis. The probabilities for profile membership and most likely membership itself were saved from the analysis, and diagnostic statistics were performed on each profile. Examination of histograms, skewness, and kurtosis indicated that measures of disruptive behavior at 2, 4, and 5 years of age were normally distributed, within each profile. Examination of box plots indicated that there were no consistent outliers across the measures of disruptive behavior within the profiles. Additionally, of the individuals with a high probability of membership in each profile, on average, 55% of them were female, and gender was not significantly related to membership in any of the profiles, $\chi^2(3, 318) = 6.23, p = .10$. It is important to note that although profile membership was forced and used to perform these post hoc analyses, all other

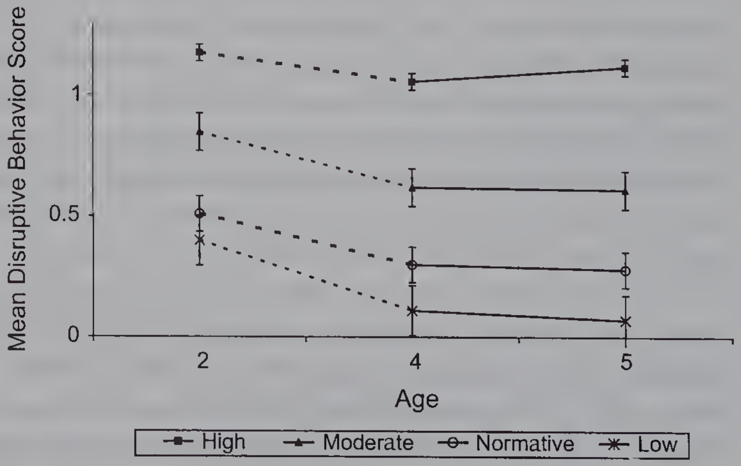

Figure 1. Profiles of disruptive behavior from 2 to 5 years of age. *Note.* Dotted lines represent the change in measurement between 2 and 4 years of age.

analyses described below were conducted within the modeling framework and in relation to the probabilities of membership in the profiles.

Description of Longitudinal Profiles

The highest profile displayed high-average levels of disruptive behavior at age 2 ($M = 1.18$, $SD = 0.09$), age 4 ($M = 1.06$, $SD = 0.04$), and age 5 ($M = 1.12$, $SD = 0.08$), and 8% of the sample had a higher probability of membership in this profile than the other three profiles. On average, this profile was just below the borderline clinical cutoff at age 2 (1.20 – 1.46; Achenbach, 1992) but by ages 4 and 5 was above the borderline clinical cutoff for boys (0.95 – 1.10; Achenbach, 1991a) and girls (0.90 – 1.00; Achenbach, 1991a); therefore, it was named the "high" profile. The second highest profile displayed average levels of disruptive behavior below the borderline clinical cutoffs, but higher than the two lower profiles, at age 2 ($M = 0.85$, $SD = 0.11$), age 4 ($M = 0.62$, $SD = 0.02$), and age 5 ($M = 0.61$, $SD = 0.04$), and 34% of the sample had a higher probability of membership in this profile than the other three profiles. Although this profile was not within the clinical range of scores, it still evidenced average elevated levels at each time point compared to the lower profiles; therefore, it was named the "moderate" profile.

Of the two lowest profiles, the second to lowest one displayed some disruptive behavior at age 2 ($M = 0.51$, $SD = 0.07$), age 4 ($M = 0.30$, $SD = 0.02$), and age 5 ($M = 0.28$, $SD = 0.02$). However, these average levels of disruptive behavior are lower than those of the profiles above. In addition, 44% of the sample had a higher probability of membership in this profile than the other three profiles. Because this profile displayed somewhat typical, but low, levels of disruptive behavior and the largest amount of the sample had a high probability of membership, it was named the "normative" profile. The lowest profile displayed low average levels of disruptive behavior at age 2 ($M = 0.40$, $SD = 0.10$), age 4 ($M = 0.11$, $SD = 0.01$), and age 5 ($M = 0.07$, $SD = 0.00$), and 14% of the sample had a higher probability of membership in this profile than the other three profiles. This profile was named the "low profile."

Prediction of Probability of Membership in Profiles

Predictors of the probabilities of membership in the above profiles were entered into the model in a hierarchical fashion (McArdle, 2005). The log likelihoods of each model were compared with the model a step before to determine whether the predictors significantly affected the model. If they did not affect the model, they were taken out to conserve power needed to detect interaction effects. First, SES was entered into the model as a covariate; however, comparison of the log likelihoods determined that it did not significantly impact the model, $\chi^2(3) = 2.0$, $p > .05$. In addition, SES did not predict the probability of membership in any of the profiles; therefore, it was removed from all further analyses. Second, the other predictors were entered in the model (frustration reactivity, physiological regulation, and maternal control). Comparison of the log likelihoods determined that they significantly impacted the model, $\chi^2(9) = 24.80$, $p < .01$. In addition, frustration reactivity and maternal control significantly predicted the probability of membership in the profiles (see Table 2). The next model included all the predictor variables and two-way interactions between the predictor variables. Interaction terms were calculated by multiplying the centered variables together. The comparison of log likelihoods between the model that included interaction terms and the model that did not determined that the two-way interactions significantly impacted the model above and beyond the main effects, $\chi^2(9) = 21.76$, $p < .01$. In addition, the interactions significantly predicted the probability of membership in the profiles (see Tables 3 & 4). Finally, a three-way interaction was tested in the model, but it did not significantly affect the model or predict membership in any of the profiles above and beyond the two-way interaction effects, $\chi^2(3) = 4.26$, $p > .05$.

There were no significant main effects that were not superseded by the interactions, and there were no significant effects differentiating the probability of

The significant two-way interactions were tested, plotted, and interpreted in accordance with Aiken and West (1991; see also Cohen, Cohen, West, & Aiken, 2003). First, the significance of each interaction was determined through the LPA (see Tables 3 and 4), where a *z* represents the test statistic for each predictor's (i.e., interaction) effect on the probability of membership in the various profiles (similar to a *t* statistic for each β in a linear regression analysis). Second, in order to plot each interaction, high and low values (±1 *SD*) as well as the mean value (0) of one predictor (the "moderator") were entered into logistic regression equations ($Y = \beta_1 X + \beta_2 Z + \beta_3 XZ + \beta_0$) to generate three regression equations denoting the effect of the other predictor (X) on the probability of membership in the profiles (Y) at each specific value of the moderator (Z). This method is similar to what is explained in Aiken and West except that in the present case the estimates used (βs) from the LPA represented the log odds associated with the probability of membership in the various profiles. The resulting plots of these values are displayed in Figures 2 and 3. Finally, in order to fully interpret the interactions, follow-up analyses were performed in line with Aiken and West to determine what range of the moderator (Z) significantly affected (i.e., was different from 0) the relation between the other predictor (X) and the probability of membership in the profile (Y). Thus, we first explored these differences around 0 and ±1 *SD*. For most of the interactions, the relation of X and Y was significantly different from 0 at these ranges of Z. However, for the interaction between observed reactivity and maternal control predicting the probability of membership in the high versus moderate profiles, these values were not extreme enough to display these effects. Therefore, we expanded our parameters by exploring the effect around ±2 *SD* of maternal control (Z), and we found that in this range, the relation between observed reactivity (X) and the probability of membership in the high profile (Y) was significantly different from 0 around + 2 *SD* of maternal control. This suggests that maternal control needed to be more extreme to affect the probability of membership in these profiles. Descriptive statistics revealed that these values of ±1 and ±2 *SD* of the "moderators" were within range of the measures. Overall, these techniques were used in order to more fully interpret each interaction. The significance of the simple slopes (i.e., whether they are different from 0), however, does not affect the significance of the overall interaction (Aiken & West, 1991).

High Profile Versus All Other Profiles

The first comparison examined was between the high profile and the other three profiles. Compared to the low profile, observed reactivity was positively related to the probability of membership in the high profile (Table 2). However, this finding was superseded by a significant interaction between maternal control and observed reactivity (Table 3; Figure 2b). In addition, compared to the moderate profile, interactions between maternal control and observed reactivity and physiological regulation were related to the probability of membership in the high profile (Table 3; Figures 2a and 2c). Finally, an interaction between children's observed reactivity and physiological regulation was related to the probability of membership in the high profile compared to the normative profile (Table 3; Figure 3a).

Compared to the moderate profile, maternal control interacted with observed reactivity in relation to the probability of membership in the high profile (Figure 2a). Therefore, the relation between observed

reactivity and the probability of membership in the high profile varied by the level of maternal control. For children with mothers with high control (control = 3.46), the level of observed reactivity was positively related to the probability of membership in the high profile, $z = 1.86$, $p = .06$; however, for children with mothers with low control (control = −1.73) or average control (control = 0), the effect of observed reactivity was nonsignificant, $z = -1.48$, $p = .14$. In addition, maternal control interacted with physiological regulation in relation to the probability of membership in the high profile as compared to the moderate profile (Figure 2c). Thus, the relation between physiological regulation and the probability of membership in the high profile varied by the level of maternal control. For children with mothers with high control (control = 1.73) or average control (control = 0), the effect of physiological regulation was nonsignificant, $z = 1.05$, $p = .29$; however, for children with mothers with low control (control = −1.73), the level of physiological regulation was negatively related to the probability of membership in the high profile, $z = -2.03$, $p = .04$. Overall, compared to the moderate profile, children were more likely to be in the high profile when high maternal control was combined with high observed reactivity or when low maternal control was combined with low physiological regulation.

Maternal control also interacted with observed reactivity in relation to the probability of membership in the high profile as compared to the low profile (Figure 2b). Therefore, the relation of observed reactivity to the probability of membership in the high profile varied by the level of maternal control. For children with mothers high on control (control = 1.73), the level of observed reactivity was positively related to the probability of membership in the high profile, $z = 2.44$, $p = .01$; however, the effect of observed reactivity for children with mothers low on control (control = 1.73) or average on control (control = 0) was nonsignificant, $z = -0.78$, $p = .44$. This result is similar to the interaction of maternal control and observed reactivity that differentiated the moderate profile from the high profile.

Finally, observed reactivity interacted with physiological regulation in relation to the probability of membership in the high profile as compared to the normative profile (Figure 3a). Therefore, the relation of physiological regulation to the probability of membership in the high profile varied by the level of observed reactivity. For children high on observed reactivity (reactivity = .43), the level of physiological regulation was negatively related to the probability of membership in the normative profile, $z = -2.45$, $p = .01$; however, the effect of physiological regulation for children low on observed reactivity (reactivity = −.43) or average reactivity (reactivity = 0) was nonsignificant, $z = -1.10$, $p = .27$. Consequently, children with high observed reactivity and low physiological regulation were more likely to be a member of the high profile as compared to the normative profile.

Low Profile Versus All Other Profiles

The second comparison was between the low profile and the other three profiles (Tables 2 and 4). Comparisons between the high and low profiles were discussed earlier and are not repeated. Both observed reactivity and maternal control were related to the probabilities of membership in the normative and moderate profiles in comparison to the low profile (Table 2). However, these effects were superseded by interaction effects (Table 4). Observed reactivity interacted with physiological regulation in relation to the probability of membership in the low profile compared to the normative profile (Figure 3b). Therefore, the relation of physiological regulation to the probability of membership in the low profile varied by the level of observed reactivity. For children low on observed reactivity (reactivity = −.43), the level of physiological regulation was positively related to the probability of membership in the low profile, $z = 3.25$, $p = .00$; however, the effect of physiological regulation for children high on observed reactivity (reactivity = .43) or average on observed reactivity (reactivity = 0) was nonsignificant, $z = -1.10$, $p = .27$. Overall, the probability of membership in the low profile was greater for children with low observed reactivity and high physiological regulation.

Discussion

The current investigation explored whether distinct longitudinal profiles of disruptive behavior across early childhood could be differentiated in a sample of girls and boys. In addition, observed frustration reactivity, physiological regulation, and maternal controlling behavior were examined for their joint effects on the probability of membership in the profiles. Theoretically, children's level of emotional reactivity, their ability to modulate that reactivity, and maternal behaviors that support or undermine these skills are all integral to social development (Calkins & Degnan, 2006). Furthermore, children's patterns of reactivity and regulation are thought to influence how maternal behavior is related to disruptive behavior over time.

The first goal of the study was to examine longitudinal profiles of disruptive behavior, from 2 to 5 years of age, using a semiparametric group-based statistical approach. Multiple developmental patterns of disruptive behavior were expected to emerge due to individual differences in disruptive behavior in toddlerhood and the development of behavioral regulation skills across childhood (Loeber & Stouthamer-Loeber, 1998; Moffitt, 1993). As expected, the LPA identified four profiles of disruptive behavior: a *high* profile, representing high levels of disruptive behavior reaching borderline clinical levels by age 5; a *moderate* profile, representing an elevated level of disruptive behavior at age 2 and more moderate levels at ages 4 and 5; a *normative* profile, representing moderate levels of disruptive behavior at age 2 and lower levels at ages 4 and 5; and a *low* profile, representing low levels of disruptive behavior at each age. Overall, the profiles identified in the current study support the number and composition of those trajectories of childhood externalizing behaviors found in past research (e.g., Hill et al., 2006; Shaw et al., 2003). Using a semiparametric approach to examine externalizing behavior across early childhood, there is consistent evidence for a high group, a moderate group, a low group, and a varying fourth group, with the high group typically representing 3%–14% of the sample (NICHD Early Child Care Research Network, 2004; Shaw et al., 2003). The present study identified four profiles, and 8% of the sample had a high probability of membership in the highest profile. Thus, there seems to be some consistency across studies in the patterns of disruptive behavior found in early childhood.

The second goal of this study was to explore possible predictors of these longitudinal profiles in order to further understand the etiology of developmental pathways of disruptive behavior. The joint effects of observed frustration reactivity, physiological regulation, and maternal control were examined on the probability of membership in the four profiles. Although it was hypothesized that the three predictors would all jointly relate to the probability of membership in the various profiles, the three-way interaction did not significantly impact the model or relate to the profiles. However, two-way interactions between the predictors were shown to relate to the probability of membership in the four profiles. Results revealed that maternal control interacted with observed reactivity and physiological regulation to distinguish between the probability of membership in the high profile and the moderate and low profiles. In addition, observed reactivity interacted with physiological regulation to distinguish between the probability of membership in the normative profile and the high and low profiles.

Specifically, in comparison to the high profile, the effect of observed reactivity on the probability of membership in the moderate or low profiles depended on the level of maternal control (Figures 2a and 2b). It was hypothesized that the high profile would be associated with a combination of high reactivity and low physiological regulation and higher levels of maternal control than the other profiles. As expected, children with high reactivity were more likely to be a member of the high disruptive behavior profile when their mothers were rated high on control. The level of maternal control also affected the relation of physiological regulation to the probability of membership in the moderate profile as compared to the high profile (Figure 2c). Unexpectedly, however, children with low physiological regulation were more likely to be a member of the high disruptive behavior profile when their mothers were rated low on control. Therefore, following a high profile of disruptive behavior across early childhood was related to either a combination of high maternal control and high reactivity or a combination of low maternal control and low physiological regulation. These results suggest that although maternal control may escalate child reactivity to maintain disruptive behavior problems, it may also serve as a protective factor for children with lower physiological regulation. These less regulated children might require this additional structure and direction from their mothers in order to display fewer disruptive behavior problems across early childhood. Thus, more than one constellation of maternal and child factors may increase the likelihood of having a consistently high profile of disruptive behavior across early childhood.

A second interaction between the individual child reactivity and regulation factors was found to differentiate the probability of membership in the high and normative profiles (Figure 3a). It was hypothesized that these profiles would display different combinations of the three predictors. Compared to the high profile, the normative profile was expected to show a combination of less reactivity, more regulation, and lower maternal control. As expected, for children with high observed reactivity, high physiological regulation led to a greater probability of membership in the normative profile. Thus, children's physiological regulation seemed to act as a protective factor against high levels of emotional reactivity. Whereas children who are less frustrated in general may be less likely to maintain a high disruptive behavior profile, those who are easily frustrated are at risk for doing so. Therefore, for these highly reactive children, having the physiological capacity to regulate that distress may have compensated for their temperamental nature, leading them to show lower, more normative, levels of disruptive behavior across early childhood. Without this capacity to manage their emotional reactions to frustration, these children might be more likely to display heightened levels of disruptive behavior.

Unexpectedly, the level of maternal control did not relate to any differences in the probability of membership between the high and normative profiles. Overall, maternal control may have different implications for child externalizing outcomes depending on the child's individual level of frustration reactivity and regulatory capabilities. It was hypothesized that the high profile would be associated with higher maternal control and that the normative profile would be associated with lower maternal control; however, this was not supported by the current findings. Perhaps mothers of children in the normative profile display a more moderate degree of maternal control, and this level of control may not influence the level of child disruptive behavior. In addition, for these children, maternal control may not have as profound an influence on how their reactivity or regulation contributes to their behavior problems. In fact, previous work has suggested that environmental factors have a dampened impact on children with less extreme levels of temperamental reactivity (Hane & Fox, 2007).

Observed reactivity and physiological regulation also interacted to differentiate the probability of membership in the two lower profiles (Figure 3b). It was hypothesized that these profiles would primarily differ in their level of observed frustration reactivity, with the normative profile displaying slightly more than the low profile. As expected, for children low on observed reactivity, high physiological regulation was related to having a higher probability of membership in the low profile. Therefore, children who were less reactive and more regulated were much more likely to be in the low profile than children who were more reactive or less physiologically regulated. In general, the normative profile was characterized as being less physiologically regulated and somewhat more reactive than the low profile. This result supports the notion that neither having lower emotional distress to frustrating events nor having the ability to regulate distress internally alone eliminates disruptive behavior altogether. Instead, it is the combination of both low frustration reactivity and high regulation that increases the likelihood of displaying low levels of disruptive behavior across early childhood.

Limitations

Although the present study contributes to the current literature by illuminating the complex relations among maternal behavior, frustration reactivity, emotion regulation, and longitudinal profiles of disruptive behavior, some limitations need to be addressed. Although SEMM is a useful analysis for longitudinal data, the classes (profiles) do not necessarily represent qualitatively distinct groups in the general population. Instead, they represent patterns that exist within the sample examined (Bauer & Curran, 2004). The present sample was overselected for externalizing behavior problems, and thus, the current results may not be generalizable to a randomized sample. In addition, the specific sociodemographic characteristics and measures used to describe the current sample could preclude other samples from displaying the same effects. For instance, using income level to further differentiate families with low income could be a more definitive measure of SES. The profiles identified in the current at-risk community sample will only become established with repetition and confirmation in other studies. At least one other sample of low-income boys has shown similar trajectories of conduct problems in early childhood (Shaw et al., 2003). However, future work should examine similar child and maternal factors in relation to disruptive behavior in additional samples with different demographic constellations.

Another limitation of the current study is the individual informant for the measure of disruptive behavior problems. Although the Teacher Report Form (Achenbach, 1991b) was used to confirm the level of externalizing behavior problems at 2 years of age, not every child had a day care provider at age 2, and they were not collected at 4 and 5 years of age. Similarly, the current study assessed only one example of physiological regulation to frustration. Measuring across multiple frustrating events would lend the ability to test reliability and form a more robust measure. In the future, studies should be designed to provide multiple assessments of each measure at each age point. Indeed, replication of the current findings would be enhanced if multiple informants and multiple assessments were used to test the effects of maternal and child factors on longitudinal patterns of behavior problems.

Finally, the current examination hypothesized a three-way interaction among observed frustration reactivity, physiological emotion regulation, and maternal controlling behavior. This interaction effect was not supported by the current findings. Theoretically, these aspects of the child and the environment are thought to influence each other in a transactional manner in relation to psychopathological outcomes (Calkins, 1994; Calkins & Degnan, 2006). Moreover, the two-way interactions that were observed suggest that these transactional and interactive relations most likely do exist in relation to disruptive behavior problems in early childhood. It is possible that the current sample size was not sufficient enough to capture the three-way effect above those afforded by the two-way interactions. In addition, measuring maternal behavior and child reactivity and regulation over time, and including them in the model as time-varying covariates, might help to uncover these more complex transactional relations. Finally, the measure of maternal control used in the current study may not generalize to all forms of maternal control. For instance, Bates et al. (1998) found that maternal control was related to less child reactivity when the control was aimed at decreasing dangerous behaviors that might cause harm to the child. Therefore, future studies should include measures of control in relation to play behavior and control in relation to risk-taking behavior in order to separate the possible distinguishing effects of these different forms of control on child reactivity, regulation, and disruptive behavior problems. Overall, studies should include slightly larger samples and longitudinal assessments across multiple domains in order to test these higher order interactions within a semiparametric modeling framework.

Summary and Implications

As hypothesized, four profiles of children's disruptive behavior from 2 to 5 years of age were differentiated by interactions between observed reactivity, physiological regulation, and maternal controlling behavior. Overall, results revealed that children are more likely to be in a high profile, when they display high observed reactivity combined with high maternal control or low physiological regulation combined with low maternal control. In contrast to a high profile children are more likely to be in a moderate profile when they display low observed reactivity combined with high maternal control or high physiological regulation combined with low maternal control. Moreover, children are more likely to be in a normative profile, compared to a high profile, when they display high observed reactivity combined with high physiological regulation, and children are more likely to be in a low profile, compared to a higher profile, when they display low observed reactivity combined with high maternal control or low observed reactivity combined with high physiological regulation. These findings support theory and research that posit interactive effects among emotion reactivity, regulation, and maternal behavior on externalizing behavior problems (Bates & McFayden-Ketchum, 2000; Calkins & Degnan, 2006). Furthermore, these results lend credence to a developmental psychopathological perspective, which has called for an examination of multiple developmental trajectories as well as multiple interactive child by environment processes leading to these trajectories (Kuperminc & Brookmeyer, 2006). Although the current study cannot attest to the specific mechanisms leading to these interactive processes, the findings reported here suggest that future investigations should examine the transactional mechanisms between temperament, emotion regulation, maternal behavior, and longitudinal patterns of behavior problems across early childhood.

Overall, the analysis used in the current study (i.e., LPA) improves on past methods used to identify groups. LPA allows for flexibility in profile assignment, predicts the probability of membership in a profile, and describes behavior over time even when the measurement of that behavior changes. In addition, these findings would not have been fully captured with cross-sectional or variable-oriented analyses. The differences between these methods are because LPA takes the level of disruptive behavior at each age into account, not just one time point, and allows for multiple population means rather than one mean for the whole sample. In addition, LPA accounts for missing data across the time points, allowing for increased power to detect interaction effects. In the current study, maternal control was not associated with greater disruptive behavior in general; rather, it was associated with extreme levels (high and low) of disruptive behavior across early childhood. Thus, LPA is a useful tool for examining multiple patterns of disruptive behavior during early childhood and the differentiation of those patterns with multiple indices of child and family functioning.

This study investigated dopamine receptor genes (*DRD2* and *DRD4*) and maternal sensitivity as predictors of infant respiratory sinus arrhythmia (RSA) and RSA reactivity, purported indices of vagal tone and vagal regulation, in a challenge task at 3, 6, and 12 months in 173 infant–mother dyads. Hierarchical linear modeling (HLM) revealed that at 3 and 6 months, RSA withdrawal in response to maternal separation was greater (suggesting expected physiological regulation) in infants without the *DRD2* risk allele than those with the risk allele. At 12 months, infants with the risk allele who were also exposed to maternal sensitivity showed levels of RSA withdrawal comparable to infants who were not at genetic risk. Findings demonstrate the importance of developmental analysis of gene–environment interaction.

Respiratory sinus arrhythmia (RSA), indexing the effect of the parasympathetic nervous system on the heart, is a psychophysiological marker for the regulation of arousal, state, and reactivity underlying individual differences in emotion, behavior, and personality in children (Fox & Stifter, 1989; Porges, 1991; Stifter, 1995; Stifter, Fox, & Porges, 1989). Although there are unresolved controversies in the field regarding the measurement of vagal tone (i.e., adjusting for respiration) and how measures of RSA should be interpreted (e.g., Denver, Reed, & Porges, 2007; Grossman & Taylor, 2007), the current study will use the term RSA as an index of cardiac vagal tone and RSA reactivity to challenge as an index of vagal regulation (see Porges, 2007), acknowledging the imperfect measures of vagal functioning that these indices provide.

Due to considerable individual variation in RSA functioning (RSA and RSA reactivity) and their links to behavioral and clinical outcomes, it is critical to understand better the factors that influence their development. Although several recent studies have examined RSA and RSA reactivity as the product of environmental factors (Burgess, Marshall, Rubin, & Fox, 2003; Calkins, Smith, Gill, & Johnson, 1998; Moore & Calkins, 2004; Porter, 2003; Porter, Wouden-Miller, Silva, & Porter, 2003), there has been almost no research on potential genetic correlates, although there is research suggesting some heritability for RSA reactivity (see below). Therefore, the primary goal of this study was to explore how specific genes may interact with parenting to influence development of infant RSA reactivity. This is consistent with the recent discussion of gene–environment interactions by Moffitt, Caspi, and Rutter (2006, p. 9) that suggests testing should be theoretically driven beginning with "plausible triads" (i.e., gene, environmental factor, behavioral phenotype). Although little is known

about candidate genes that contribute to RSA, there is a small literature linking dopamine genes and general cardiovascular function that may be relevant, a larger body of research linking specific dopamine genes with certain behavioral phenotypes (e.g., Amenta, Ricci, Rossodivita, Avola, & Tayebati, 2001; Yeh et al., 2006) that are, in turn, related to infant RSA functioning, and research linking infant RSA functioning to parenting (reviewed below). Based on this indirect evidence, we tested a theoretical relation between infants' RSA functioning (RSA and RSA reactivity) and candidate genes involved in regulating dopaminergic response (*DRD2* and *DRD4*) and the moderating effect that parenting may have on this relation.

To support the proposed theoretical model of gene–environment interaction, first we review the literature that links RSA functioning, parenting, and infant regulation related to social behavior. Next, we discuss the literature on genetics of vagal tone and cardiovascular functioning. Third, we review research linking the dopamine receptor genes *DRD2* and *DRD4* to phenotypes related to behavioral regulation.

RSA and Vagal Tone

Parasympathetic control over cardiac functioning (i.e., vagal tone) is related to self-regulation, temperament, affect, and attention (Bornstein & Suess, 2000). The term *vagal tone* refers to control of the heart via the vagus nerve and is typically measured as the amplitude of RSA (i.e., beat-to-beat heart period [HP] associated with respiration), a parasympathetic index of heart rate variability (Porges, 1996; Porges & Byrne, 1992) and underlying regulatory abilities in mammals (Porges, 1996). Baseline vagal tone is considered to be a stable neurophysiological mechanism underlying autonomic and behavioral reactivity that provides a measure of resting state in the absence of environmental challenge. In the extant literature, RSA is commonly equated with vagal tone; however, it is important to remember that this is only *one* of its components and that there are many other influences on heart rate variability (Grossman & Taylor, 2007). Of these various components, however, RSA has been the most consistently examined in relation to dimensions of behavioral functioning in infants. For example, higher resting RSA during infancy has been associated with less temperamental difficulty (Stifter & Fox, 1990), greater sustained visual attention (Richards & Cronise, 2000), secure attachment (Izard et al., 1991), more sociable and explorative behavior (Fox, 1989; Stifter et al., 1989), and greater behavioral reactivity (Porges, Doussard-Roosevelt, Portales, & Suess, 1994).

Porges's (2007) polyvagal theory of social engagement asserts that the autonomic nervous system enhances restoration and growth by regulating the "vagal brake," which slows down the heart (i.e., activated vagal tone) during situations that do not present a challenge. However, during times of environmental stress, these internal processes are disrupted and the autonomic nervous system increases metabolic output to deal with external demands. A decrease in RSA (or RSA withdrawal) typically occurs when an individual is involved in an activity that requires active coping (Porges 1991, 1996), at which time the vagal "brake" is withdrawn (i.e., vagal tone is inhibited) to support an increase in heart rate. When environmental demands have ceased, the brake is reengaged (i.e., vagal tone is activated) to promote decreases in metabolic output and a return to a calm state. Thus, effective vagal functioning has been related to the ability to maintain homeostasis in the face of changing demands by allowing a shift from attention on internal demands to external ones that include the use of coping strategies to regulate affective or behavioral arousal.

Withdrawal of RSA during a challenging situation has been related to positive outcomes in infancy such as higher soothability (Huffman et al., 1998), more attentional control (Huffman et al., 1998; Suess, Porges, & Plude, 1994), and better emotion regulation (Calkins, 1997; Porges, Doussard-Roosevelt, Portales, & Greenspan, 1996). Furthermore, individual differences in RSA functioning have been examined as an index of characteristics such as aggression (Mezzacappa et al., 1997) and hostility (Sloan et al., 1994) in adolescents and adults. Although supporting data (Bazhenova, Plonskaia, & Porges, 2001; Moore & Calkins, 2004) are not conclusive, this research has led to the assumption that greater RSA withdrawal during a challenge context reflects more effective regulation.

Influence of early parenting on RSA. Due to the almost complete reliance on caregivers in assisting with both physiological and behavioral regulation during infancy, improvement in self-organization of these processes emerges with age (Spangler & Grossmann, 1993; Spangler, Schiechle, Ilg, Maier, & Ackerman, 1994). The way in which caregivers respond to the needs of their infants may have an impact on developing adaptive methods to modulate physiological stress (Derryberry & Rothbart, 1984) by infants' progressively internalizing the regulation strategies used within the dyad during the earlier months (Calkins et al., 1998; Thompson, 1994).

RSA functioning, therefore, is a potential mediator of the relation between parenting and changes in infant emotional reactivity and regulation across development (see review by Propper & Moore, 2006). A number of studies have explored developing patterns of RSA functioning as the result of qualities of the infant–caregiver relationship and found that these qualities are, indeed, related to physiological functioning. Infants of dyads that spent more time in joint communicative sequences with continuous adjustment of behaviors in response to their partners, allowing for a range of emotional experience, had higher resting RSA than those in dyads that did not display this dyadic regulation (Porter, 2003). Moore and Calkins (2004) found that as early as 3 months of age, infants of dyads exhibiting lower synchrony showed higher physiological reactivity during a normal play episode, less RSA withdrawal during a situation meant to elicit distress, and more difficulty returning to previous levels of reactivity and RSA following distress. Yet another study found that infants of more responsive parents displayed greater regulation of heart rate (RSA was not assessed) during a challenge task than infants of less responsive parents (Haley & Stansbury, 2003).

A recent study using the same sample as in the current report examined the link between infant–mother attachment relationships and infant change in RSA during the Strange Situation Procedure (SSP; Hill et al., 2008). Findings revealed that infants classified as insecure–avoidant displayed greater cardiac arousal and RSA withdrawal during separation and reunion episodes of the procedure than did infants classified as securely attached. This finding suggests that these infants may have been experiencing high levels of internal distress while minimizing behavioral displays of their distress. These infants appeared to recruit internal resources to actively cope with an external challenge and, therefore, may have relied on self-regulation to a greater degree than other infants, who may have relied more on their mothers. These findings are consistent with earlier discussions of the attachment relationship in terms of emotion regulation strategies (Cassidy, 1994). Cassidy suggested that the attachment relationship influences, over time, the behavioral strategies used by infants to successfully interact and respond to stress within that relationship. Infants classified as insecure–avoidant may show a behavioral pattern in response to a stressful situation (i.e., separation from mother) that minimizes their emotional expressions, perhaps because they have learned from experience to rely less on the attachment relationship as a source of comfort (Belsky, Rovine, & Taylor, 1984; Main & Solomon, 1986).

Genetics of RSA. Only a handful of infant studies have examined the associations of RSA functioning among family members. Healy (1992) studied monozygotic and dizygotic twins between the ages of 11 and 35 months and found no evidence of heritability of baseline RSA. Similarly, Bornstein and Suess (2000) looked at the relation between mother and child baseline RSA at 2 months and at 5 years of age and found no concordance within dyads. They did find, however, that RSA reactivity (measured as the baseline-to-challenge task difference) was concordant between mother and child at both time points, increasing from 2 months of age ($r = .23$) to 5 years of age ($r = .42$), suggesting an increase in some shared style of physiological response to environmental challenges within the dyad over time. Through repeated interactions, the mother's behavioral approach, or affective style, may transmit to her offspring a characteristic style of autonomic responsiveness. Additionally, genetic differences may contribute to observed changes in cardiovascular regulation and may be more pronounced during conditions of stress or challenge (Boomsma, Snieder, de Geus, & van Doornen, 1998; Kupper et al., 2005).

Support for this genetic hypothesis has been found in several behavioral genetics studies. Twin studies have reported RSA heritability estimates ranging from 13% to 55% (Boomsma, van Baal, & Orlebeke, 1990; Kupper et al., 2005; Singh et al., 1999; Sinnreich, Friedlander, Luria, Sapoznikov, & Kark, 1999; Voss et al., 1996). Of note, two twin studies found an increase in genetic variance associated with RSA during a challenging situation versus RSA at rest. The first one found that roughly 50% of the variance in RSA measured in adolescence was explained by genetic factors during two challenge tasks (i.e., reaction time and mental arithmetic), whereas only 25% of the variance was explained by genetic factors during a resting period (Boomsma et al., 1990). Similarly, a study of middle-aged twins found that heritability of RSA was 35% and 43% during two comparable challenge tasks (i.e., reaction time and mental arithmetic) and decreased to approximately 31% at rest (Snieder, Boomsma, Van Doornen, & De Geus, 1997). Results of these studies support the conclusion that there is genetic influence on RSA that may be more marked during a challenge.

However, heritability estimates do not tell us anything about the specific genes that contribute to RSA functioning or in what way they do so. Only a small number of studies have examined specific genes as potential contributors to measures of cardiac functioning, most are animal models, and none of which we are aware has examined relations between specific genes and RSA. The results of the current study may provide a targeted direction for examining this relation. In addition, to date, research examining associations between specific genes and cardiovascular functioning has proceeded primarily from a health psychology approach, selecting candidate genes based on their association with disease conditions or other aspects of biological functioning. As outlined earlier, our approach was to select candidate genes based on association with behavioral phenotypes of interest. In addition, innovative prior research on the genetics of cardiovascular functioning has been conducted with samples ranging in age from adolescence to adulthood, without consideration of genetic contributions to the developing vagal system during infancy. Furthermore, in the extant literature, there is a lack of attention given to experiential factors, which may interact with genetic effects to better predict physiological outcomes (Gottlieb, 1998, 2003). The current study aimed to explore the dopamine receptor genes *DRD2* and *DRD4* that were selected on the basis of associations with behavioral phenotypes related to RSA functioning as potential predictors of RSA functioning in infancy and to examine possible interactions between these genes and infants' experience with parenting sensitivity across early infancy.

In addition to association with behavioral phenotypes, *DRD2* and *DRD4* are implicated in biological mechanisms of cardiovascular functioning. Dopamine regulates cardiovascular functioning by acting on the central and peripheral nervous systems, vascular smooth muscles, the heart, and the kidneys (Jose, Eisner, & Felder, 1999). Five distinct dopamine receptor genes have been identified and classified into two groups known as the "D1-like" super family (D1 and D5 receptors) and the "D2-like" super family (D2, D3, and D4 receptors; see Hyde, Knable, & Murray, 1996), each with its own molecular structure, mRNA coding and anatomical distribution, and chromosomal location (reviewed in Sibley & Monsma, 1992). The D2-like family of dopamine receptors has consistently been linked to the central nervous system regulation of blood pressure (Amenta et al., 2001; Bek, Eisner, Felder, & Jose, 2001; Jose, Eisner, & Felder, 1998; Yeh et al., 2006) and hypertension (Amenta, et al., 2001; Linthorst, van Giersbergen, Gras, Versteeg, & De Jong, 1994; Vaughan, van den Buuse, & Roland, 1999). There are a significant number of D2-like receptors found in the vagal complex (Hyde et al., 1996), suggesting that the *DRD2* and *DRD4* receptors are an important component of neural mechanisms regulating visceral function, including the cardiovascular system. Nevertheless, considerable research remains to be done to specify functional relations between these genes and RSA functioning in humans.

Dopamine Genes and Behavior

DRD2. Research on the associations of *DRD2* and behavioral characteristics has been limited to adolescence and adulthood, with no studies done in infancy. Variations in *DRD2* have been related to several dimensions of adult personality, including novelty seeking, sensation seeking, and aggressiveness (Cloninger, Adolfsson, & Svrakic, 1996; Noble et al., 1998). The risk allele of *DRD2* (i.e., minor *Taq*1 A1 allele) has been related to high novelty seeking scores (Noble et al., 1998; Suhara et al., 2001). Possessing the *Taq*1 A1 allele of *DRD2* has also been suggested as a risk factor for conduct disorder (Comings et al., 1996; Lu, Lee, Ko, & Lin, 2001), which is not surprising considering its association with impulsivity (Wiers, Sergeant, & Gunning, 1994) and disinhibition (McGue, Slutske, Taylor, & Iacono, 1997). Furthermore, several types of substance abuse have been associated with the *Taq*1 A1 allele of *DRD2*, including alcoholism (Blum et al., 1991; Noble et al., 1994), nicotine (Comings et al., 1996; Noble et al., 1994), and opiate dependence (Lawford et al., 2000). Finally, this allele of *DRD2* has also been associated with other addictive behaviors such as pathological gambling (e.g., Comings et al., 1996). These results are consistent with expectations, as the *Taq*1 A1 allele of *DRD2* has been reported to be associated with a decrease in D2 dopamine receptor availability (Pohjalainen et al., 1998) and the number of receptor binding sites is lowest in A1 homozygotes. Therefore, given that D2 dopamine receptors have an inhibitory function in the dopaminergic system, a lower availability of these receptors may translate into less behavioral control.

DRD4. The *DRD4* gene contains a repeated sequence polymorphism within its coding sequences that changes the length of the receptor protein that has been shown to have a moderate functional significance (Asghari et al., 1994). Individuals with longer versions of the polymorphism (L-*DRD4*; six to eight repeats) have significantly higher novelty seeking than those with the shorter version (S-*DRD4*; two to five repeats); the shorter the allele, the more efficient it is in binding dopamine (Plomin & Rutter, 1998), suggesting that the L-*DRD4* allele is a risk allele. Research on the associations of *DRD4* and behavioral characteristics has been conducted with adult and adolescent samples and more recently with infants and young children. Variations in *DRD4* have been related to dimensions of adult personality such as novelty seeking, characterized by excitability, impulsiveness, and high exploratory behavior (Benjamin et al., 1996; Ebstein, Nemanov, Klotz, Gritsenko, & Belmaker, 1997; Noble et al., 1998), cigarette smoking (Shields et al., 1998), pathological gambling (Pérez de Castro, Ibáñez, Torres, Sáiz-Ruiz, & Fernández-Piqueras, 1997), and alcoholism (George, Cheng, Nguyen, Israel, & O'Dowd, 1993). L-*DRD4* in 4-year-old children was associated with aggression as reported by mothers (Schmidt, Fox, Rubin, Hu, & Hamer, 2002). In 3-year-old children, L-*DRD4* was associated with lower intensity of emotional reactions such as happiness, anger, and sadness than S-*DRD4* (DeLuca et al., 2001). Infants at 12 months of age with the L-*DRD4* allele showed less anger-related negative emotionality than did infants with the S-*DRD4* allele in an anger-inducing task (Auerbach, Faroy, Ebstein, Kahana, & Levine, 2001). Earlier we discussed that individuals who fail to show expected RSA withdrawal in response to challenge situations may not be as reactive to those situations as most infants; infants with the L-*DRD4* may be just such an example.

In summary, the *DRD2* and *DRD4* dopamine receptor genes are associated with personality characteristics and clinical disorders that are impulsive, reward seeking, and addictive in nature. These characteristics, overall, appear to be related to a lack of regulatory ability and behavioral control, suggesting an association between dopamine and RSA, which is also highly associated with regulatory ability and behavioral control. It is important to note, however, as with most direct gene – behavior associations, many of the earlier mentioned relationships have failed to replicate (e.g., Gebhardt et al., 2000; Gelernter et al., 1997; Jönsson et al., 1998). This failure to replicate may be due to differences in sample composition, such as ethnicity or sex, or to differences in phenotype measurements. However, of interest in the current study is the possibility that it is due to the lack of research attention to environmental factors.

Goals of the Current Study

Although studies have examined the influence of parenting on the development of RSA functioning (baseline RSA and RSA reactivity to challenge), thus far, little research has examined the genetic underpinnings of this process. Research has suggested a relationship between the *DRD2* and *DRD4* genes and characteristics that are related to impulsivity and behavioral dysregulation. Similarly, studies of RSA functioning have found associations between expected RSA withdrawal in response to challenge and better behavioral regulation. Thus, the current study used a theoretically driven approach to examine the association between these genes and RSA functioning. To explore possible gene – environment mechanisms that may influence the development of RSA functioning across early infancy, this study examined the interaction between these genes and early maternal parenting sensitivity as precursors of later RSA functioning.

Method

Participants

Participants were drawn from the Durham Child Health and Development Study (DCHDS), a longitudinal sample consisting of 206 healthy, full-term infants who were followed from 3 months to 3 years of age. Families were recruited from a largely urban community via fliers and postings at birth and parenting classes, as well as through phone contact via birth records. Approximately equal numbers of European American (EA) and African American (AA) families were sampled from low- and high-income groups. Infant's race was determined by the mother (or primary caregiver); income status was assessed based on the size of the family in relation to their household income in accordance with the 2002 Federal Poverty Guidelines. Demographic information was collected during the first visit at 3 months of infant age and was updated at each subsequent visit.

Infant – mother dyads from the DCHDS were seen within a week of infants' 3-, 6-, and 12-month birthdays. Dyads that completed the mother – infant free-play task at the 6-month visit ($N = 173$) made up the initial sample for this report. However, only those dyads with infants that had complete heart rate data at *any* of the three visits, as well as complete *DRD2* genetic data, were included in analyses ($N = 142$). The final sample for analyses consisted of 67 males and 75 females. Seventy-two mothers reported their infants to be AA and 70 EA. At recruitment, the mean age of mothers was 27.8 ($SD = 5.63$, range = 18 – 40 years). Fifty-one percent of mothers reported having some college education, 49% had a high school education or some vocational training, and 44% of mothers were currently employed. Sixty-nine families reported incomes that were classified as below poverty and 73 as above poverty. Of the 142 participants with complete *DRD2* data, 11 fewer participants had complete *DRD4* data. Those with incomplete *DRD4* data did not differ by ethnicity or income.

Missing Data

Thirty-three of the dyads recruited at 3 months of infant age did not have complete data for the 6-month free-play task due to attrition ($N = 27$) or problems with coding due to video quality ($N = 6$). An additional 15 infants were missing genetic data due to difficulties with genotyping ($N = 8$) or refusal to provide a cheek cell sample ($N = 7$). Of the remaining infants, 18 were missing heart rate data at each of the three assessments. Eighty-three dyads had cardiac data at only one time point, 76 dyads had cardiac data at two time points, and 31 dyads had complete cardiac data across all three of the time points. The reasons for the missing data at each assessment, as well as the number of infants missing data per visit, are: heart rate monitor experienced problems or failure (3 months = 5, 12 months = 2), collected data contained too many artifacts to use due to movement or removal of equipment by infant (3 months = 10, 6 months = 14, 12 months = 7), infant could not finish the task due to fussiness or extreme upset (3 months = 3, 12 months = 2), or the dyad did not complete the visit or task (6 months = 4, 12 months = 7). No systematic differences associated with missing data by ethnicity or income group were found.

Procedure

Visits were conducted both at the family's home and in the lab. At each visit, infants and their mothers participated in several joint and individual tasks followed by a standardized interview and completion of demographic questionnaires by mother. Although assessments were done every 3–6 months until the child reached 36 months of age, the present study examined data only from visits that occurred when infants were 3, 6, and 12 months old when observational tasks designed to assess infants' responses to maternal separation were conducted. These visits were targeted because although the mother–infant separation tasks differed between early infancy and age 12 months, they each provided an age-appropriate standardized assessment of infants' responses to withdrawal of maternal attention, thus allowing us to compare infants' physiological regulation in response to a typical, developmentally appropriate stressor. All tasks were videotaped for later coding.

Measures

Mother–infant free play (6-month home visit). To evaluate maternal behavior during interactions with infants, mothers were provided a standard set of toys and instructed to interact with their children as they normally would if playing during some free time on a typical day. The task lasted 10 min and was videotaped for later coding.

Free-play interactions were coded by two independent coders who were unaware of the study's hypotheses. From these observations, seven subscales of maternal behavior were coded (sensitive responsiveness, intrusiveness, detachment, positive regard, negative regard, stimulation of cognitive development, and animation). Coders were trained to reliability until interclass correlation coefficients of .80 or greater were established and maintained with criterion coders (and for each individual pair of coders). All interactions were double coded and final scores were agreed on by conferencing. An overall maternal sensitivity composite was created (guided by factor analyses) by aggregating the scores for five of the subscales, including sensitivity–responsiveness, positive regard stimulation of development, animation, and detachment–disengagement (reverse scored). Similar composite scores for maternal sensitivity have been used by the National Institute of Child Health and Human Development Study of Early Child Care (1997), the Family Life Project (Blair, Granger, Willoughby, Kivlighan, & the Family Life Project Key Investigators, 2006), and other reports based on the current DCHDS sample (Mills-Koonce et al., 2007).

Mother–infant still-face procedure (3-month home visit and 6-month laboratory visit). To assess infants' responses to maternal separation, the mother–child dyad participated in the still-face procedure (SFP; Tronick, Als, Adamson, Wise, & Brazelton, 1978). Mothers placed their children in an infant seat situated on a table and then sat on a chair directly in front of them. The normal play episode consisted of mothers playing with their babies as they normally would. After this 2-min episode, mothers were told to turn away from their infants for 15 s, after which time they turned back and began the still-face episode. During the still-face episode, mothers were asked to look at their children for 2 min without any facial movements or vocalizations. Mothers were then asked to turn away from their infants for another 15 s, which was followed by a 2-min reunion episode in which mothers were told to respond to their infants in any way that they felt was appropriate. Only HP and RSA data from the still-face episode of the SFP were used for the current analyses. During this time, infants experienced an episode of withdrawal of maternal attention, which requires them to regulate their own physiological arousal without the help of their mothers. We focused specifically on this episode of the procedure because it was individual, rather than dyadic, level of regulation that was of interest in the current study and because the episode was considered most analogous to the maternal separation task at 12 months.

Strange situation procedure (12-month laboratory visit). To assess infants' responses to maternal separation at 12 months, mothers and their infants were observed in the strange situation procedure (SSP; Ainsworth, Blehar, Waters, & Wall, 1978). Throughout the procedure, infants were exposed to eight brief episodes of increasing stress, including two mother – infant separations and reunions. The current study focuses on the first episode of mother – infant separation (fourth episode) at which time mothers leave the room and the infant is alone with a stranger for 3 min. Only HP and RSA data from this first separation episode of the SSP were used for the current analyses because the second episode of separation (sixth episode) elicited high levels of distress from almost all infants, creating a possible ceiling effect.

Cardiac monitoring. At the start of each visit, the experimenter placed two disposable pediatric electrodes on the infant's chest while he or she was seated in a baby seat or mother's lap. The electrodes were connected to a preamplifier, from which the output was transmitted to a heart interbeat interval (IBI) monitor (Mini Logger; Mini-Mitter/Respironics, Bend, OR) for R-wave detection. The infant wore a smock with a large pocket in which the monitor was placed. Once the monitor was securely in place and the infant was acclimated, an electronic signal was sent to the monitor by the experimenter (by manually pressing a button on the monitor) in order to mark the start of a 2- to 4-min baseline measure of IBI activity. During this period of time, mothers were asked not to interact with, or provide toys to, their infants so that stimulation was minimized and infants' IBI could be measured accurately during a neutral and calm state. At the completion of baseline, another electronic signal was used to mark the end of this episode. IBI data were continuously collected during the rest of the visit, with electronic signals to the monitor to mark the start and end of each task. During the SFP and the SSP, electronic signals marked the start and end of each episode.

Buccal cell collection (12-month laboratory visit). DNA was obtained through the collection of infant buccal cells (i.e., cheek cells). The experimenter put on latex gloves before handling any supplies and rubbed the inside of the infants' inner cheek and gums for 20 s with a Q-tip. The Q-tip was then immediately placed into a pint-sized zip-loc bag, sealed, and put into a storage freezer where it remained until sent to the laboratory for processing. Cheek cells for DNA isolation and analysis were sent to a genetics laboratory at North Carolina State University, Raleigh, NC. All the genotyping was done blind to the study's hypotheses and outcomes.

Data Reduction

Computation of RSA and HP. At the completion of each visit, a data file containing infant IBI data for the period of collection was transferred from the monitor to a computer in the laboratory. Such activities as bodily movements, infants tugging on electrodes, physical force to the monitor, and other such disruptions may affect IBI collection by recording artifactual points within the cardiac data. Thus, the IBI data files were edited and analyzed using Mxedit software (Delta Biometrics, Bethesda, MD) by two Mxedit reliable researchers. Editing the files consisted of scanning the data for outlier points relative to adjacent data and replacing those points by dividing them or summing them so that they would be consistent with the surrounding data. Due to difficulties in collecting cardiac data from infants of this age (i.e., pulling on electrodes, equipment failure), only participants who had full and sufficient data with less than 10% editing were used in the current analyses.

The present study used Porges' (U.S. Patent No. 4,510,944, 1985) method of calculating RSA and HP. The estimate of RSA is reported in units of $\ln(\text{ms})^2$. RSA was calculated every 15 s for the baseline period and for each episode of the SFP and SSP. These epoch durations are typical for studies of short-duration tasks (Huffman et al., 1998). The mean RSA of the 15-s epochs within each episode was used in subsequent analyses. Larger values of HP indicate slower heart rate and larger values of RSA suggest greater vagal tone.

Computation of change in RSA and HP. To assess RSA reactivity, change in RSA (ΔRSA) was measured as the difference between baseline RSA and RSA during the still-face episode of the SFP at 3 and 6 months and the difference between baseline RSA and RSA during the fourth episode of the SSP at 12 months. Following previous research (Calkins, 1997; Moore & Calkins, 2004), difference scores were computed by subtracting episode RSA from baseline RSA, such that sign indicated direction of change, with positive values indicating greater RSA withdrawal (the expected response) and negative values indicating an increase in RSA during the challenge situation. Change in HP (ΔHP) was measured in the same way as ΔRSA (baseline HP minus episode HP). Positive values of HP indicated an increase in heart rate (the expected response) during the challenge situation and negative values indicated a decrease in heart rate. This method provided an index of change relative to each infant's baseline level.

Researchers have used both difference score and residual score methods to assess change in RSA. In the current data set, correlations between residual scores and difference scores for infants' RSA and HP ranged from .96 to .99. However, due to concerns that the use of difference scores might underestimate the effect between ΔRSA and infant genotype, we ran analyses using both difference scores and residualized scores and obtained the same results. Because the two scores have slightly different meanings, with residual scores indicating change if all participants started out equal in terms of baseline RSA and difference scores indicating raw change from baseline-to-challenge context, we chose the difference score method, as we believed that was most consistent with our research question.

Genotyping. Genomic DNA was extracted from each salivary sample using the Puregene DNA extraction kit by following the manufacturer's protocol for DNA isolation from 1 ml of body fluid. Saliva samples yielded DNA in adequate quantities for genotyping (approximately 200 μg/ml). Genotyping of the 48-bp repeat in Exon III of the *DRD4* gene was performed as previously described (Propper, Willoughby, Halpern, Cox, & Carbone, 2007). The genotypes s/s, s/l, or l/l were assigned to each individual where s is the short allele and l is the long allele. Based on previous results (Anchordoquy, McGeary, Liu, Krauter, & Smolen, 2003; Benjamin et al., 1996; Schmidt et al., 2002), polymorphisms made up of homogeneous short alleles (s/s) were classified as Short (S-*DRD4*) and heterogeneous polymorphisms (s/l and l/l) were classified as Long (L-*DRD4*).

Genotyping of the *DRD2* gene was performed by polymerase chain reaction amplification using the forward and reverse primers: 5′-ccgtcgacggctggccaagttgtcta-3′ (D2F1) and 5′-ccgtcgacccttcctgagtgtcatca-3′ (D2R1; Miyake et al., 1999). The amplicon was subsequently digested with the restriction enzyme, *Taq*α1 (New England Biolabs, MA). This results in digestion products of the A1 allele (310 bp) and the A2 allele (180 + 130 bp). The allele status of *DRD2* A_1^+ (A_1/A_1 and A_1/A_2 genotypes) and A_1^- (A_2/A_2 genotype) were assigned to each individual based on previous studies (see Noble, 2003).

Results

Descriptive Statistics and Bivariate Relations Among Covariates

Forty-six percent of the sample carried the risk A_1^+ allele of *DRD2*, and 36% of the sample carried the risk L-*DRD4* allele of *DRD4*. There was a significant difference in distributions of *DRD2* polymorphisms as a function of ethnicity, with AA infants more likely to have the risk A_1^+ allele of *DRD2* than EA infants, $\chi^2(1) = 3.99$, $p < .05$. This population stratification is consistent with existing research (Barr & Kidd, 1993). The impact of genetic differences by ethnicity, and the most appropriate way to address it in research designs, is currently the source of ongoing debate (Hoggart et al., 2003; Thomas & Witte, 2002; Wacholder, Rothman, & Caporaso, 2002). Because ethnicity in this study was measured by participants' self-report and individuals often are unaware of their full genetic heritage, making the measure of ethnicity subject to error, and because analyzing the groups separately would substantially attenuate power, the current analyses examined the two ethnic groups together but included ethnicity as a covariate in the model. There was no significant difference in the distribution of the *DRD4* polymorphisms as a function of ethnicity.

Maternal sensitivity was significantly higher in EA families, $t(170) = 4.08$, $p < .001$ (see Table 1) and higher income families, $t(170) = 6.10$, $p < .001$. AA infants exhibited a lower mean value of ΔRSA, reflecting less RSA withdrawal at 3 months, $t(145) = 2.23$, $p < .05$, and 6 months, $t(75) = 4.01$, $p < .05$, during the still-face episode of the SFP, and they had higher baseline RSA, on average, at 12 months, $t(99) = 3.00$, $p < .01$.

On average, infants with the *DRD2* risk allele (A_1^+) had mothers who were less sensitive than infants

Table 1
Means and Standard Deviations of Variables by Ethnicity and DRD2 *Polymorphisms*

*$p < .05$. **$p < .01$. ***$p < .001$.

without the risk allele (A_1^-), $t(154) = 2.10$, $p < .05$ (see Table 1). Infants with the A_1^+ allele exhibited lower values of ΔRSA at 3 months, $t(128) = 2.92$, $p < .01$, and 6 months, $t(71) = 2.69$, $p < .01$, during the still-face episode than those without the risk allele (A_1^-). No mean differences were observed for maternal sensitivity or vagal functioning at any time point. As seen in Table 2, baseline RSA was stable over time, although ΔRSA was not. Baseline RSA was related concurrently to ΔRSA at 3 and 6 months but not at 12 months. Maternal sensitivity was uncorrelated with physiological variables.

Model Specification

HLM were estimated using SAS proc mixed in order to examine changes in children's vagal functioning (baseline RSA, ΔRSA) over three time points from 3 to 12 months. This procedure allowed for the control of the nonindependence of observations due to the same individuals being repeatedly assessed over time. An HLM approach also accounts for missing-at-random outcome data, allowing the use of all available data for the outcome of interest (Little & Rubin, 1987; Raudenbush & Bryk, 2002). Restricted maximum likelihood was used in reporting model parameters, and degrees of freedom were estimated using the Satterthwaite method. Because of the correlations between demographic factors and model parameters, ethnicity and income were included in all HLM. Models were estimated for *DRD2* and *DRD4* separately. There were no significant findings for *DRD4*, so the following reports results from the *DRD2* analyses only.

Preliminary Analyses: Vagal Functioning Over Time

Trajectories for levels of baseline RSA and levels of ΔRSA were first analyzed to assess normative change over time in these components of RSA functioning. Controlling for ethnicity and income, mean levels of baseline RSA increased from 3 to 12 months of child age by 0.25 *SD* (based on the distribution at 3 months of age), $F(2, 173) = 4.50$, $p < .05$. Mean levels of ΔRSA during the challenge task decreased from 3 to 12 months of child age, $F(2, 135) = 7.84$, $p < .001$. Because of the change in protocol to accommodate developmental changes in infants during the 1st year of life, it is not possible to determine whether changes in ΔRSA over time are due to child development or due to methodological artifact. Therefore, the following analyses of ΔRSA were conducted using *z* scores for ΔRSA rather than raw values. This approach is consistent with the main goal of the current research to analyze the effects of genetic and environmental factors on vagal functioning at different points in time as compared to analyzing their effects on trajectories of vagal functioning.

Predictors of Child Vagal Functioning Across 3 to 12 Months

Baseline RSA. There were no effects of *DRD2*, maternal sensitivity, or their interaction on baseline RSA. There was a main effect of ethnicity, $F(1, 242) = 9.46$, $p < .05$, indicating that AA infants exhibited higher levels of baseline RSA. Consistent with descriptive analyses presented earlier, this effect was moderated by time, $F(2, 135) = 3.90$, $p < .05$, such

$^{\dagger}p < .10$. $^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$.

that only AA infants displayed increases in baseline RSA over time, $F(2, 184) = 5.86, p < .01$.

Change in RSA. There was a significant effect of *DRD2* on ΔRSA, $F(1, 242) = 9.46, p < .01$, such that the risk A_1^+ allele was associated with lower levels of ΔRSA (i.e., less RSA withdrawal). This effect was moderated by a significant three-way interaction between *DRD2*, maternal sensitivity, and time, $F(2, 242) = 4.26, p < .05$. Probing this interaction revealed that at early ages, there were significant main effects of child genotype on ΔRSA. Children with the A_1^+ allele were observed to have lower ΔRSA, indicating less RSA withdrawal, than children without the risk allele at 3 months of age, $F(1, 107) = 6.02, p < .05$, and at 6 months of child age, $F(1, 63) = 4.23, p < .05$ (see Table 1). At 12 months of child age, a significant interaction between maternal sensitivity and child genotype was observed, $F(1, 39) = 10.02, p < .05, \eta^2 = .13$. Probing this interaction revealed that high maternal sensitivity was associated with greater ΔRSA, indicating greater RSA withdrawal for infants with the risk A_1^+ allele, $F(1, 33) = 5.29, p < .05, R^2 = .15$. As seen in Figure 1, the A_1^+ risk allele was associated with lower levels of ΔRSA at 3 and 6 months, and by 12 months, infants with highly sensitive mothers were observed to have comparable levels of ΔRSA regardless of their *DRD2* polymorphism. Cells means in Figure 1 are adjusted for covariates.

Given the exploratory nature of the current research, post hoc analyses were conducted to assess a possible confound between *DRD2* and ethnicity. First, in the model analyzed earlier, when controlling for child genotype and maternal sensitivity, the main effect of ethnicity on ΔRSA (reported in the Descriptive Statistics section) was no longer significant. Second, the interaction between sensitivity and ethnicity was examined and found to be nonsignificant, $F(1, 242) = 3.04, p < .1, \eta^2 = .06$. Figure 2 illustrates the effect of maternal sensitivity on ΔRSA for children of different genotypes, separately by ethnic groups.

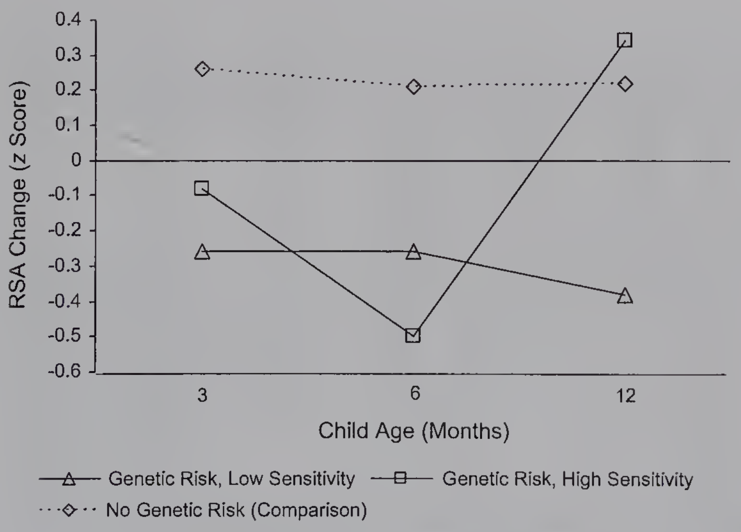

Figure 1. Maternal sensitivity moderates the relation between *DRD2* and infant change in respiratory sinus arrhythmia at 12 months.

Discussion

The primary goal of the present study was to explore genetic and environmental contributors to the development of RSA functioning related to social engagement across early infancy. The dopamine receptor genes *DRD2* and *DRD4* were selected on the basis of known associations with behavioral regulatory problems, which are, in turn, associated with infants' RSA functioning. The results of this study indicated that gene and environmental factors interacted in the development of RSA and RSA reactivity across 3–12 months, highlighting the importance of developmental analyses of gene–environment interactions (Gottlieb & Halpern, 2002).

Infants carrying the A_1^+ allele of *DRD2*, which has been identified as a risk factor for problematic outcomes in adolescents and adults related to novelty seeking, aggressiveness, and impulse control disorders, showed significantly lower levels of RSA withdrawal in reaction to a task designed to be mildly distressing at 3 and 6 months of age. As RSA withdrawal in response to challenge is a purported indicator of effective physiological regulation, these findings suggest that the *DRD2* genetic risk for behavioral disorders may be, in part, mediated by RSA functioning. Over time, however, maternal sensitivity moderated change in infant RSA reactivity to challenge. Although infants carrying the risk A_1^+ allele consistently exhibited less RSA withdrawal at 3 and 6 months, infants with the risk allele who were also exposed to sensitive maternal caregiving displayed an increase in RSA withdrawal in reaction to a distressing social situation by 12 months of age, reaching levels that were comparable to infants who were not at genetic risk.

RSA withdrawal in response to a distressing task is the typical response in infancy, and there is a body of research suggesting it indicates effective physiological regulation. Nevertheless, there are other interpretations of the current findings that cannot be ruled out. First is that infants who did not show RSA withdrawal were simply not distressed. In the current study, there is no way of accurately determining whether an infant did or did not become distressed by the procedures. Infants' behavioral and physiological indicators of distress are commonly uncorrelated in infancy (e.g., Gunnar, Mangelsdorf, Larson, &

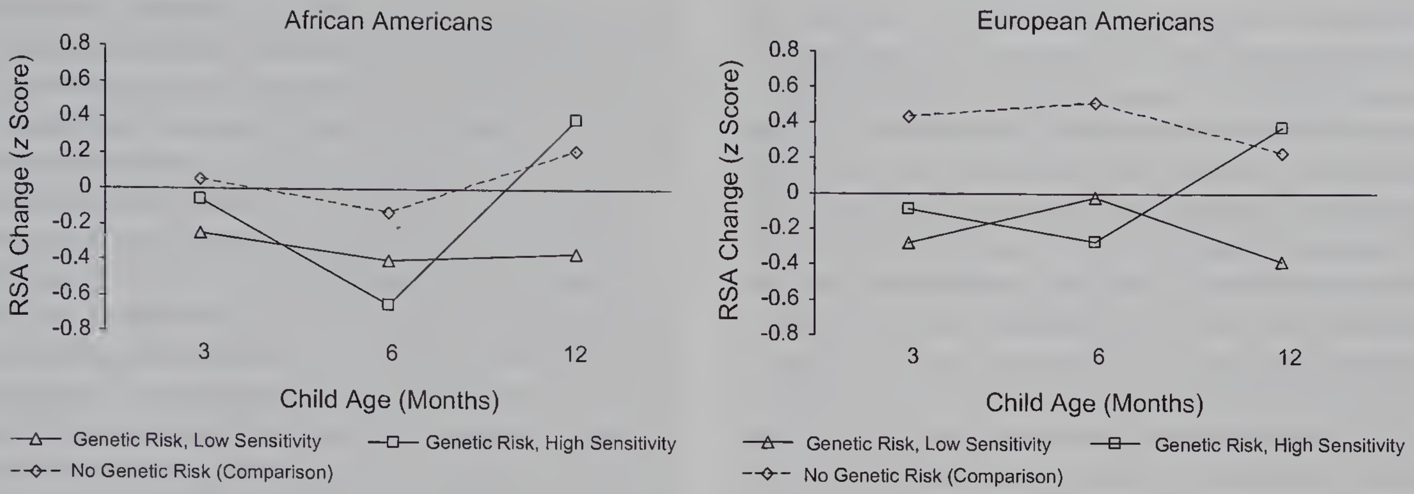

Figure 2. Interaction between maternal sensitivity and *DRD2* Risk Group by Ethnicity.

Hertsgaard, 1989; Weinberg & Tronick, 1996; cf. Bazhenova et al., 2001; Haley & Stansbury, 2003; Moore & Calkins, 2004). Measures of change in HP, which suggest arousal, were highly positively correlated with RSA reactivity, suggesting that infants who were more aroused showed greater RSA withdrawal. However, HP does not provide a measure of physiological arousal that is independent of parasympathetic influences. In future research, measures of sympathetic reactivity are needed, such as skin conductance, which has been used successfully to assess sympathetic reactivity in infants' responses (Ham & Tronick, 2006).

Second, an increase in RSA in response to a challenge task may indicate increased attention and is related to higher levels of exploratory behavior (DiPietro, Porges, & Uhly, 1992). Given that the risk A_1^+ allele of *DRD2* has been found to be associated with novelty seeking and risk-taking behavior in adults, it may be that infants with this genetic profile found the challenge tasks to be novel and interesting rather than distressing.

Third, in interpreting the interaction between genetic risk and maternal sensitivity over time, there are several possible explanations for the increase in RSA withdrawal seen for infants with the risk A_1^+ allele of *DRD2* and highly sensitive mothers. One is that genetic risk carries an associated deficit in effective vagal functioning (indicated by a lack of or diminished RSA withdrawal to an expected stressor), but as a result of experience with a sensitive mother who presumably has provided support for the development of self-regulatory skills, these infants gradually acquired more effective physiological regulation by 12 months. Alternatively, these infants may already have had adequate physiological regulation but, until they accumulated sufficient experience with a highly sensitive mother, did not become distressed at separation from her. Analogously, their counterparts in the genetic risk group who did not have highly sensitive mothers may either have had a deficit in effective vagal functioning or did not find the separation from mother distressing because of either an innate sense of novelty, as discussed earlier, or because it is not particularly distressing to be separated from a mother who is insensitive. This would be consistent with research finding that infants of depressed mothers were less likely to become distressed in response to mothers' still-face than other infants (Field, 1984).

It is also likely that, as with adults, there are individual differences in type of reactivity to stressors. Some individuals respond primarily with parasympathetic activation, some with primarily sympathetic activation, and some with activation of both systems. As stated earlier, additional measures of sympathetic reactivity are needed in future research to help to identify which of these many possible interpretations are most valid, and much larger sample sizes are needed to determine whether individual differences in patterns of autonomic reactivity can be identified in early infancy.

Although our theoretical model was based, in part, on associations between behavioral phenotypes and *DRD2* and *DRD4* genes, we found an association between infant RSA functioning and the *DRD2* gene only. This could be a sample specific finding. Additional research needs to be done to replicate this finding as well as to understand better the biological basis of the functional relation between *DRD2* and RSA functioning. Although a detailed discussion of the biological structure and function of dopamine receptors is beyond the scope of this article (see Missale, Nash, Robinson, Jaber, & Caron, 1998, for review), extant findings on the relationship between the dopaminergic system and cardiovascular functioning, mainly from animal models, may help explain the current findings. The "D2-like family" of dopamine receptors, which includes the *DRD2* and *DRD4* genes examined in the current study, has been found in the human vagal complex (Hyde et al., 1996), and dopamine receptors have been found in regions of the brain that are known to control cardiovascular function (van den Buuse, 1998), suggesting that they are an integral part of neural mechanisms that regulate cardiovascular function. However, the *DRD2* gene specifically has been associated with hypertension in both humans (Thomas, Tomlinson, & Critchley, 2000) and rats (Linthorst, De Lang, De Jong, & Versteeg, 1991; Linthorst et al., 1994). Furthermore, Li et al. (1998) found hypertension in mice to be caused by increased activity of the adrenergic nervous system after disruption to the *DRD2* gene (as cited in Bek et al., 2001), which suggests an indirect effect of dopamine on cardiac functioning. Injection of dopamine into the nucleus ambiguus of mice caused bradycardia (i.e., abnormally slow heart beat) due to the excitation of *DRD2* receptors on vagal inhibitory neurons controlling heart rate (Chitravanshi & Calaresu, 1992). Taken together, this research suggests that the relation between *DRD2* and RSA functioning found in the current study may reflect functional distinctions between the *DRD2* and *DRD4* receptor genes' effects on the vagal system. Our findings may also suggest that the relation between *DRD2* and behavioral regulatory problems is mediated by RSA functioning, whereas the relation between *DRD4* and behavioral regulatory problems is not or is related indirectly to RSA functioning.

Several methodological issues set an important context for interpreting the results. First, expected difficulties associated with obtaining valid cardiac data from young infants at three different time points resulted in a relatively small sample size. Second, because this was a longitudinal study, the challenge tasks in which we assessed infants' change in RSA needed to be developmentally appropriate. The challenge selected—maternal separation – is known to elicit stress responses from infants at various ages, thus remained consistent across age in the study. The context in which maternal separation occurred, however, had to change to accommodate developmental changes in the degree of separation that infants would find stressful. Although the still-face paradigm and the SSP are different procedures, each presents the infant with an age-appropriate disruption in social interaction that involves a removal of maternal attention, and there is evidence to show that infants' responses to the still-face paradigm predict their responses to the SSP (e.g., Cohn, Campbell, & Ross, 1991), suggesting some functional equivalence between the two procedures. It is difficult to say with certainty that the task used at 12 months was eliciting the same emotional or physiological response from infants as the task used at 3 and 6 months, but this is a fundamental dilemma of developmental research.

Another methodological issue is the possibility that population stratification could have resulted in a confound, which can arise when the outcome of interest differs between ethnic populations for nongenetic reasons while the distribution of alleles also differs by ethnicity. In our sample, AA infants were significantly more likely to have the A_1^+ allele than EA infants, consistent with extant research on the frequency of the *DRD2* A1 allele, where reported frequencies for EAs were found to be the lowest of 16 ethnic populations (Barr & Kidd, 1993). Although the issue of population stratification is an important one to consider, the degree to which this presents a problem remains controversial (Hoggart et al., 2003; Thomas & Witte, 2002), and reviews of the literature have found that the extent of population stratification bias has been exaggerated (Cardon & Palmer, 2003) and is likely to be small (Wacholder et al., 2002). Furthermore, in this study, ethnicity was assessed by mothers' self-report, and the sample was not likely to be accurately stratified in terms of genetic ancestry, especially in admixed populations where individuals may not be completely sure of their precise ancestry (Ziv & Burchard, 2003).

Exploring the possible confound suggested that, in terms of RSA reactivity, there was not a significant differential sensitivity to parenting for children of different ethnicities after controlling for genotype. Although not conclusive, this supports the interpretation of a gene–environment interaction across ethnic groups and suggests that ethnicity was not a confound. Ethnic differences found in other recent studies of genetic effects on physiological and behavioral outcomes (Propper et al., 2007; Williams et al., 2003), however, indicate the need to examine this issue in future research using larger and ethnically homogeneous samples or new methods that are being developed for detection and correction using within-family analyses or genome-wide covariates (Risch, Burchard, Ziv, & Tang, 2002; Rosenberg, Li, Ward, & Pritchard, 2003).

Finally, because there was a dearth of empirical research on which to base a search for specific candidate genes that affect the development of RSA and RSA reactivity, the justification for examining dopamine receptor genes in this study was indirect, theoretical, and based on known associations between dopamine and specific behavioral outcomes and between specific behavioral outcomes and infants' RSA reactivity. Although not ideal, this approach has been used to initiate or narrow the search for specific genes so that subsequent, molecular linkage studies may prioritize candidate genes in a hypothesis-driven search.

Keeping in mind the limitations and caveats noted earlier, the current findings provide an important first step in understanding possible genetic and environmental influences on the development of infants' RSA functioning. Although there are various interpretations of the current findings, one possibility is that these results show how infants' interactions with their caregivers over time could provide the necessary experience to effect change on genetic expression. The observed developmental change for one group of infants may reflect the impact of life experience; over time, reactions may be attributed not only to innate physiological mechanisms but also to experiential history (Sroufe, 1995). Between 3 and 12 months, infants undergo substantial developmental change, and recent developments in disparate areas of research are converging on the conclusion that interpersonal experiences strongly shape not just behavior but neural, physiological, and physical development (e.g., Siegel, 2001).

The 1st year of life is an important time for infants to develop regulatory abilities to adaptively cope with their environment. Parents may influence the way in which infants respond to situations, behaviorally and physiologically, through their help in alleviating negative emotions, reinforcing positive ones, and structuring the environment in which infants experience emotion. In the current study, at 3 and 6 months of age, infants may have exhibited RSA responses to their environments based on the influence of specific genetic polymorphisms of *DRD2* rather than parenting. However, the contributions of *DRD2* to the expression of physiological responses to the environment during the early weeks of life are likely to be, over time, only one of the many other factors that play a role in the development of these characteristics (Auerbach et al., 1999). By 12 months of age, specific experiential factors (i.e., parenting) may exert an increasingly potent influence on infants, as they become more likely to understand, interpret, remember, and apply past experiences to novel situations (Sroufe, 1990).

Thus, when examining gene – environment interactions, it is important to take into account the cumulative nature of environmental influences. Moffitt, Caspi, and Rutter (2005, p. 476) stated that "although the effects of a pathogen measured at a single point may be weak, the cumulative effects of extended or repeated exposure to that pathogen are often strong . . . most risks derive from long-standing situations rather than acute events." The current study provides empirical support for this assertion. At 3 and 6 months of age, infants may not have had enough exposure to maternal behavior for it to exert an effect; by 12 months, however, the cumulative effect of maternal behavior may be more pronounced.

In contrast to the findings for RSA reactivity, there were no genetic effects of *DRD2* on baseline RSA or its development. This is consistent with the findings of behavioral genetics studies discussed earlier in which the genetic variance associated with RSA reactivity during a challenge task was higher than that associated with baseline RSA (Boomsma et al., 1990; Kupper et al., 2005; Snieder et al., 1997). The current finding provides further evidence that conditions of challenge may elicit stronger individual differences in vagal regulation, leading genetic differences to become more pronounced (Boomsma et al., 1998).

The current findings may help to elucidate some of the nonreplications in the literature regarding the association of *DRD2* and adult personality and psychological outcomes. Extant research has reported associations between the risk allele of *DRD2* (A_1^+) and disorders related to the inability to regulate behavior (e.g., Comings et al., 1996; Noble et al., 1994), whereas other studies have failed to find these relationships (e.g., Edenberg et al., 1998). Our findings suggest that the risk allele may indeed be related to problems with physiological regulation during a stressor (i.e., lack of RSA withdrawal). However, when combined with a positive environment, the risks of this allele may diminish over time. Although the specific mechanisms that link *DRD2* and RSA functioning cannot be determined by these exploratory analyses, we provide initial data suggesting that this link may exist. Future studies should include analyses of genes and environment over time to further clarify their joint contribution to phenotypic outcomes (e.g., Caspi et al., 2002).

Another interesting finding of the current study was that infants with the risk allele (A_1^+) had mothers who were less sensitive than those without the risk allele (A_1^-). A strictly genetic explanation suggests that infants with the A_1^+ allele may have inherited this genotype from their mothers and that lack of sensitivity is associated with behavioral regulatory problems associated with this genetic risk. Another likely explanation is a "passive" gene – environment correlation, indicating that the influence of the mother's genotype on her own behavior influences her child's experiences and development (Rutter, 1997). From this perspective, our results are consistent with what we would expect if children possessed the same risk allele as their mothers; they may be at increased risk due to both genetic and environmental susceptibility for behavioral or physiological regulatory problems. Finally, children shape and select their own experiences by the way in which they act on their environment (Plomin, DeFries, & Fulker, 1988). An infant who is genetically predisposed to exhibit less RSA withdrawal in response to challenge may have more trouble regulating behavior. Infants with behavioral problems may be more difficult to care for, leading mothers to display less sensitive behavior in response.

Future Directions

This study is the first, to our knowledge, to address the interplay of genetic and environmental factors as they contribute to the development of early RSA functioning in humans. Findings have identified a number of important directions for future research, in addition to those already noted earlier. Research in molecular genetics is moving away from single gene association studies. Future research would benefit from examining multiple candidate genes in the same model (gene–gene interactions) as well as including haplotypes (i.e., sets of single alleles or closely linked genes that tend to be inherited together). Studies of this nature would require much larger sample sizes to detect multigene, multienvironment interactions.

Furthermore, differences found in maternal sensitivity as a function of ethnicity, with AA mothers being rated as less sensitive than EA mothers, are similar to reports in the literature that AA mothers show fewer displays of physical affection and warmth toward toddlers than EA mothers (Berlin, Brooks-Gunn, Spiker, & Zaslow, 1995; Bradley, Corwyn, McAdoo, & Garcia Coll, 2001). It may be the case that cultural norms dictate different parental behaviors, as well as the way in which that behavior is interpreted (Bradley et al., 2001; Deater-Deckard, Dodge, Bates, & Pettit, 1996; McLoyd & Smith, 2002). Coding systems may not be sensitive to these cultural differences. Future research should examine mechanisms, such as socioeconomic status or coding bias, which may underlie these differential effects.

In summary, the findings of the current study are the first to identify the effects of a gene–environment interaction between parenting in infancy and a specific gene that has been implicated in difficulties in behavioral self-regulation. Our findings suggest that maternal sensitivity may moderate potential negative effects of the risk allele of the dopamine gene *DRD2* on infant RSA functioning as early as 12 months of age. Although additional research is needed, the current study provides a very exciting and innovative base for future research.

Seven hundred thirty-one income-eligible families in 3 geographical regions who were enrolled in a national food supplement program were screened and randomized to a brief family intervention. At child ages 2 and 3, the intervention group caregivers were offered the Family Check-Up and linked parenting support services. Latent growth models on caregiver reports at child ages 2, 3, and 4 revealed decreased behavior problems when compared with the control group. Intervention effects occurred predominantly among families reporting high levels of problem behavior at child age 2. Families in the intervention condition improved on direct observation measures of caregivers' positive behavior support at child ages 2 and 3; improvements in positive behavior support mediated improvements in children's early problem behavior.

Problem behavior in middle childhood and adolescence is a predictable outgrowth of problematic adjustment in early childhood (Brook, Whiteman, Cohen, & Tanaka, 1992; Brook, Whiteman, Gordon, & Cohen, 1986; Campbell, Shaw, & Gilliom, 2000; Caspi, Moffitt, Newman, & Silva, 1998; Hawkins, Lishner, Catalano, & Howard, 1986; Lyons-Ruth, Zeanah, & Benoit, 1996; Shaw, Gilliom, Ingoldsby, & Nagin, 2003; Vicary & Lerner, 1983). Longitudinal studies begun with children as young as age 3 years (e.g., Caspi et al., 1998) have revealed an association between early behavior problems and long-term profiles of risk, including substance dependence in young adulthood.

Our study was motivated by three principles: (a) the prevention of problem behavior in children and adolescents must be family centered and ecologically focused; (b) for the most effective long-term impact on health, empirically supported family interventions must be brief and therefore more cost effective and must be embedded in existing service systems (Hoagwood & Koretz, 1996); and (c) developmental transition points such as toddlerhood, school entry, and early adolescence offer unique opportunities for health promotion and risk reduction because child and family behaviors reorganize at these points (Dishion & Stormshak, 2007; Sameroff & Fiese, 1987).

Intervening during the first of these transition points, when the child begins to walk and becomes physically autonomous (ages 1–2 years), is an important strategy for preventing adolescent problem behaviors such as delinquency and substance use. Parent–child interaction patterns during this transitional developmental period are challenged by normative increases in child mobility, language, independence, and physical aggression and noncompliance. Families' adaptation to this developmental transition forms the basis for subsequent developmental stages (Shaw, Bell, & Gilliom, 2000; Shaw & Gross, in press).

It is increasingly clear that parenting practices are at the core of early-onset problem behavior and adjustment problems and are integral to the solution

---

(Dishion & Stormshak, 2007). Negative and neglectful parenting practices when children are age 2 are prognostic of later problem behavior, whereas the predictive validity of the child's behavior emerges somewhat later in development (Shaw & Gross, in press). It is clear that the covariation between early parenting practices, children's problem behavior, and later adjustment problems is multidetermined, including factors such as temperament, social context, and proximal factors describing the parents' adjustment (Shaw et al., 2000). Specifically, we know that among children assessed to be at genetic risk for problem behavior, punitive and harsh parenting practices greatly exacerbate that risk (Caspi et al., 2002). Studies of the genetic contributions to the development of antisocial behavior suggest a vulnerability model, in that some children are simply more vulnerable to pathogenic environments. The upside of this conclusion is that vulnerable children, in theory, will be more responsive to positive changes in the environment, such as those effected by systematic interventions. Intervention research with young adults diagnosed with liability for schizophrenia reveal that an emphasis on positive family management reduces the negative affective tone of the family and the mental health difficulties associated with the disorder (Falloon et al., 1985).

Thus, it is important to go beyond telling parents what they should not do (e.g., use harsh punitive parenting) and to identify and promote positive parenting practices that prevent the development of children's problem behavior and replace negative parenting practices. In their children's early years, parents can support the development of the children's competence by using a combination of parenting practices that includes a warm, trusting relationship (Shaw et al., 2000), attentive involvement (Glik, Greaves, Kronenfeld, & Jackson, 1993), positive reinforcement for skill development (Forgatch & Toobert, 1979; Supplee, Unikel, & Shaw, 2007), and proactively structuring situations to promote the development of self-regulation and minimize problem behavior (Gardner, 1994; Gardner, Sonuga-Barke, & Sayal, 1999). Positive parenting strategies such as these are consistent with what has been referred to as *positive behavior support strategies*, a prevalent and effective educational behavior management principle that emphasizes the use of nonaversive, reinforcing adult–child interactions to promote development (e.g., Horner & Carr, 1997; Sugai, Horner, & Sprague, 1999).

A key early intervention strategy, therefore, is to strengthen parents' use of positive behavior support strategies in early childhood to manage and prevent common toddler problem behaviors (Gardner et al., 1999; Gardner, Ward, Burton, & Wilson, 2003; Sanders, 1999). Consistent with this notion, Pettit and Bates (1989) found increased parent–child play and social contact in the 1st and 2nd years of a child's life to be associated with fewer conduct problems at age 4. Similarly, Gardner et al. (1999) found that if parents of toddlers timed their positive interaction strategies to anticipate troublesome situations, 2 years later the risk of child behavior problems was diminished. Successfully engaging parents in positive behavior support practices may help increase the frequency of seemingly mundane parent–child interactions such as conversation and play, which are formative to language development and self-regulation (Baldwin, 1995; Baldwin, Bill, Desjardins, Irwin, & Markman, 1996; Hart & Risley, 1995).

As shown in Figure 1, the infusion of positive behavior support strategies in early development is thought to reduce the development of problem behavior and thereby decrease the likelihood of reactive parenting strategies and coercive escalations (Patterson, 1982; Snyder, Edwards, McGraw, Kilgore, & Holten, 1993). Parent–child coercive interactions serve to increase the likelihood of new forms of child misbehavior and more serious forms of antisocial behavior (Dumas, Lemay, & Dauwalder, 2001; Patterson, Reid, & Dishion, 1992). These early-onset problem behaviors also tend to disrupt children's development of positive skills and adjustment to school (Campbell, Pierce, Moore, Marakovitz, & Newby, 1996; Dishion, 1990; Ingoldsby, Shaw, & Garcia, 2001; Shaw, Owens, Vondra, Keenan, & Winslow, 1996). Accordingly, problem behavior in middle childhood as identified by teachers or parents is prognostic of continuity to adolescence, including more serious antisocial activity (e.g., arrest), substance use, and

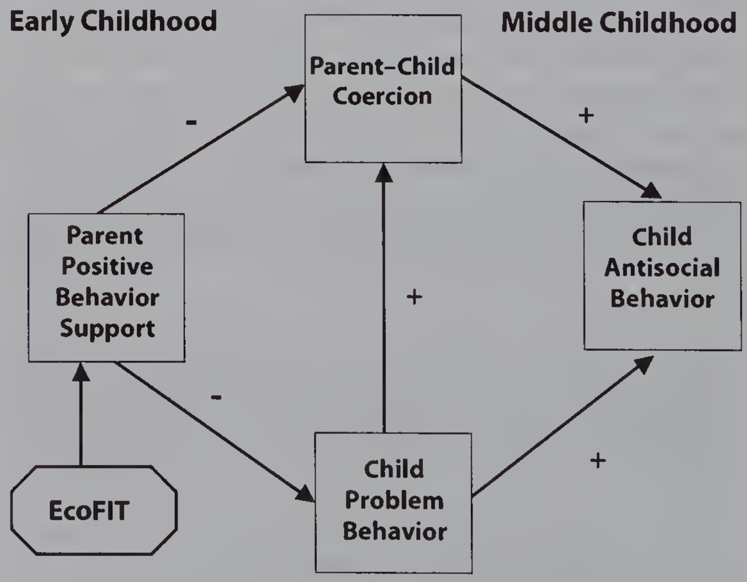

Figure 1. Theoretical framework for the early steps intervention.

sexual activity begun between ages 11 and 15 (Loeber & Dishion, 1983; Patterson et al., 1992; Shaw & Gross, in press). In addition to exacerbating child problem behavior, coercive parent–child interactions and a history of child antisocial behavior often undermine the parent–child relationship (Patterson & Dishion, 1988), making efforts to intervene at later developmental stages more challenging because parents may have "given up" their efforts to influence and socialize their child (Dishion, Nelson, & Bullock, 2004; Dishion & Patterson, 1992).

Family Interventions

If a small subset of children has the highest rate of problem behavior and psychopathology within a community and these risk factors can be reliably identified in early childhood, intervention programs logically would prioritize these children's families. If effective, the prevention efforts would improve parent–child interactions and reduce risk among the most vulnerable youth, on a variety of adjustment indices. The Family Check-Up (FCU) intervention specifically targets disrupted and unskilled family management practices in early childhood to reduce and prevent later problem behavior and focuses on parenting factors and variables found to compromise parenting quality (e.g., temperament, parental well-being) that have also been shown to be directly related to trajectories of persistent problem behavior. The term *family management* describes a collective set of parenting skills known to be highly related to child success (Bullock & Forgatch, 2005; Forgatch, Bullock, & Patterson, 2004; Patterson, 1982; Patterson et al., 1992).

That family-centered strategies are effective for reducing child problem behavior is strongly supported in the treatment and prevention science literatures across developmental periods (e.g., Brody et al., 2004; Conduct Problems Prevention Research Group, 2002; Dishion & Patterson, 1992; Eddy & Chamberlain, 2000; Forgatch & DeGarmo, 1999; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998; Kazdin, 2003; Liddle, 1999; Sanders, 1999; Spoth, Redmond, & Shin, 1998), including early childhood (Brinkmeyer & Eyberg, 2003; Olds, 2002; Olds et al., 1997; Webster-Stratton, 1990). Family-centered interventions have undergone a critical shift in the past 20 years, moving from a treatment model that is delivered to clients in clinic settings to a prevention model involving proactive recruitment of parents to engage in interventions in home and community settings such as schools, day care, and community support services (Gardner, Burton, & Klimes, 2006; Hutchings et al., 2007; Shaw, Dishion, Supplee, Gardner, & Arnds, 2006).

It is not difficult to argue that the earlier one intervenes with a family, the easier it is to make significant developmental changes and reduce the likelihood of early-starting conduct problems and later drug-use risk. There are three reasons for the early intervention hypothesis. First, early interventions target the child behavior before more serious forms of antisocial behavior develop. Noncompliant and oppositional behavior is easier to remediate than are lying, stealing, and proactive aggression. Targeting behavior early is expedient because a child's ecology expands with development and moves from home into school and neighborhood settings that are less predictable and that involve relationships with teachers (Pianta, Steinberg, & Rollins, 1995) and same-age and older peers (Dishion, Duncan, Eddy, Fagot, & Fetrow, 1994; Ingoldsby & Shaw, 2002). Eventually, peers may transform reactive aggression into proactive aggression and may support other forms of negative behavior (Poulin & Boivin, 2000). By adolescence, peers can become a powerful context within which delinquency, drug use, and sexual experimentation are embedded (Capaldi, Crosby, & Stoolmiller, 1996; Dishion & Owen, 2002; French & Dishion, 2003; Patterson, Dishion, & Yoerger, 2000). Thus, family interventions initiated in early childhood are more likely to meet the objective of preventing a variety of later behavior problems.

The second advantage of early intervention is that parents are probably younger and have undergone fewer development transitions themselves, including having multiple children and multiple partner transitions, and they may likely engage in fewer high-risk behaviors that compromise their own health. In particular, divorce and remarriage have disruptive effects on the parent–child relationship and child adjustment, and although these transitions can be opportune times to intervene (e.g., Martinez & Forgatch, 2001), it certainly would be better to prevent their occurrence in the first place. Early interventions by Olds and colleagues not only reduced the number of caregiver relationship transitions but also the number of ensuing children (Olds, Hill, Robinson, Song, & Little, 2000; Olds et al., 1997).

Third, the sense of optimism caregivers have regarding the possibility of parent–child relationship change is much higher during their offspring's early childhood. As noted earlier, parents' motivation to change may be significantly reduced after years of predominantly acrimonious interchanges with a child compared with when they are parents of toddler-age offspring. We found that parents of adolescents were more likely to drop out of behavioral family therapy treatment than were parents seeking treatment with younger children (Dishion & Patterson, 1992). In the FCU model, only 25% of the parents of adolescents engaged in the intervention (Connell, Dishion, Yasui, & Kavanagh, 2007), whereas more than 75% of families in early childhood trials engaged in the FCU (Shaw et al., 2006).

The empirical evidence for the effectiveness of family-centered interventions during early childhood is impressive. The pioneering work of Webster-Stratton and colleagues is exemplary. By using videotaped examples and promoting the use of systematic, behavioral therapy-based parenting skills that build a productive parent–child relationship and strengthen family management, significant improvements have been observed and replicated (e.g., Webster-Stratton & Taylor, 2001). In the family management model, the interventions are offered in a parent group format, and caregivers' discussions about the videotaped examples are a compelling source of change.

The Ecological Approach to Family Intervention and Treatment Model

Despite these promising findings, current forms of empirically supported family interventions arguably require more efficient and brief interventions that can be rolled out via service delivery systems that have contact with large numbers of children and families (Hoagwood & Koretz, 1996). The ecological approach to family intervention and treatment (EcoFIT) was designed with a public health focus to ensure that the needs of a wider range of children and families are met, from prevention to treatment. The focus also ensures efficiency in terms of cost and in delivery in settings that reach a large number of children, such as public school systems (Dishion & Stormshak, 2007). The intervention is "ecological" in that it is designed to improve children's adjustment across settings (home, school, and neighborhood) by motivating positive behavior support practices in those settings. Two key features of the intervention are that it is assessment driven and tailored to the needs of youth and families as revealed by family observations, assessments in extrafamilial contexts (e.g., schools), and reports from important individuals in the child's life (e.g., parents, teachers, youth when of age), and that typically, intervention is brief.

The EcoFIT model is predicated on the FCU (Dishion & Kavanagh, 2003), which is a brief parenting intervention that emphasizes motivation to change (Miller & Rollnick, 2002). The FCU involves three sessions. The first step is a meeting with parents to explore their perceptions and concerns regarding their family setting and child's behavior. The second step is a comprehensive assessment that includes videotaping parent–child interactions. The third step is a structured feedback session that is based on the results of the assessment and that emphasizes parenting and family strengths yet draws attention to possible areas of change. The intervention is motivational in that it stimulates caregivers to address key problems in parenting either on their own or with the support of a professional. Interventions that follow the FCU are thus tailored to each family's needs on the basis of the assessment and of the parents' motivation to change. Consequently, some parents may focus on only one dimension of their parenting practices, unlike with conventional parenting intervention programs that tend to emphasize a standard curriculum of parenting practices to all parents.

The tailored, adaptive, and motivational aspect of the intervention results in relatively brief interventions. The application of the EcoFIT to families of young adolescents within the school setting revealed that an average of six sessions for the highest risk families during the course of 2–3 years resulted in enduring reductions in drug use and problem behavior and improved parental monitoring practices (Connell et al., 2007; Dishion, Nelson, & Kavanagh, 2003).

In pilot work leading to this study, we applied the FCU intervention to high-risk families of toddlers involved in a national family nutrition and health program for young families referred to as the Women, Infants, and Children Nutrition Program (WIC). We randomly assigned 120 families of toddlers to either WIC as usual or WIC with one FCU at child age 2 and found that the intervention reduced subsequent problem behavior and improved parent involvement at child ages 3 and 4, respectively (Shaw et al., 2006). Moreover, videotaped home observation sessions showed that random assignment to the FCU had resulted in improvements in caregivers' use of proactive parenting practices and reduced child negative behavior at age 3 (Gardner, Shaw, Dishion, Burton, & Supplee, 2007). These findings generally fit with those of two dissertation projects that used the FCU with families with toddlers and revealed improved parenting and reduced child problem behavior (Jones, 2004; O'Leary, 2000).

The WIC study of the FCU was limited in terms of sample size, intervention services offered to the families, and use of only male children from an urban community. Our current study, referred to as the Early Steps Multisite Study, remedies these limitations. First, the sample includes 731 at-risk families; half were randomly assigned to the FCU/EcoFIT intervention and the remainder to WIC as usual. Second, the families were recruited from three geographically and culturally diverse regions, including metropolitan Pittsburgh, PA; suburban Eugene, OR; and rural Charlottesville, VA. The sample also reflects cultural diversity, including African American, European American, and Latino families. Third, we used the entire EcoFIT model in that families were provided additional services following the FCU, consistent with an adaptive, tailored approach to intervention. We examined outcomes on parent reports of child problem behavior and direct observations of positive behavior support practices, including positive reinforcement, proactive parenting, parent involvement, and joint-attention verbal interaction.

In this study, we hypothesize that families at high risk involved in WIC and randomized to the EcoFIT would (a) report reductions in problem behavior from child age 2 to 4 years compared with control families, (b) show increases in caregiver involvement and direct observations of positive behavior support practices at child ages 2 and 3 compared with control participants, and (c) show that reductions in problem behavior would be mediated by improvements in positive behavior support practices, as measured by home visitor ratings and direct observations of parent–child interaction.

Method

Participants

Participants included 731 mother–child dyads recruited between 2002 and 2003 from WIC programs in the metropolitan areas of Pittsburgh, PA, and Eugene, OR, and in and outside the town of Charlottesville, VA. Families were contacted at WIC sites and invited to participate if they had a son or daughter between age 2 years 0 month and 2 years 11 months, following a screen to ensure that they met the study criteria by having socioeconomic, family, and/or child risk factors for future behavior problems. Risk criteria for recruitment were defined at or above 1 *SD* above normative averages on several screening measures in the following three domains: (a) child behavior (conduct problems, high-conflict relationships with adults), (b) family problems (maternal depression, daily parenting challenges, substance-use problems, teen parent status), and (c) sociodemographic risk (low education achievement and low family income, relevant to WIC criterion). Two or more of the three risk factors were required for inclusion in the sample.

Recruitment. As shown in Figure 2 and in Table 1, of the 1,666 families who had children in the appropriate age range and who were contacted at WIC sites across the three study sites, 879 met the eligibility requirements (52% in Pittsburgh, 57% in Eugene, and 49% in Charlottesville) and 731 (83.2%) agreed to participate (88% in Pittsburgh, 84% in Eugene, and 76% in Charlottesville). The children in the sample had a mean age of 29.9 months (*SD* = 3.2) at the time of the age 2 assessment.

Of the 731 families (49% female), 272 (37%) were recruited in Pittsburgh, 271 (37%) in Eugene, and 188 (26%) in Charlottesville. Across sites, primary caregivers self-identified as belonging to the following ethnic groups: 28% African American, 50% European American, 13% biracial, and 9% other groups (e.g., American Indian, Native Hawaiian). Thirteen percent of the sample reported being Hispanic American. During the 2002–2003 screening period, more than two thirds of those families enrolled in the project had an annual income of less than $20,000, and the average number of family members per household was 4.5 (*SD* = 1.63). Forty-one percent of the population had a high school diploma or general education diploma (GED), and an additional 32% had 1–2 years of post–high school training.

Age 4 feedback received	66.6	71.9	53.2	65.3

Retention. Of the 731 families who initially participated, 659 (90%) were available at the 1-year follow-up and 619 (85%) participated at the 2-year follow-up when children were between 4 years and 4 years 11 months old. At ages 3 and 4, selective attrition analyses revealed no significant differences in project site; children's race, ethnicity, or gender; levels of maternal depression; or children's externalizing behaviors (parent reports). Furthermore, no differences were found in the number of participants who were not retained in the control versus the intervention groups at both age 3 ($n = 40$ and $n = 32$, respectively) and age 4 ($n = 58$ and $n = 53$, respectively).

Measures

Demographics questionnaire. A demographics questionnaire was administered to the mothers during the child ages 2, 3, and 4 visits. This measure included questions about family structure, parental education and income, parental criminal history, and areas of familial stress.

Maternal depression. We used a brief but valid indicator of adult depression referred to as the Center for Epidemiological Studies on Depression Scale (CES–D; Radloff, 1977). The CES–D is a well-established and widely used 20-item measure of depressive symptomatology that was administered to mothers at the child ages 2 and 3 home assessments. Participants report how frequently they have experienced the listed depressive symptoms during the past week on a scale ranging from 0 (*less than 1 day*) to 3 (*5–7 days*). Items are summed to create an overall depressive symptoms score. For the current sample, internal consistencies were .76 and .75 at the ages 2 and 3 assessments, respectively.

Early childhood problem behavior. The Child Behavior Checklist (CBCL) for ages 1.5–5 (Achenbach & Rescorla, 2001) is a 99-item questionnaire that assesses behavioral problems in young children. Mothers completed the CBCL at the child ages 2, 3, and 4 home assessments. The CBCL includes one broadband factor that assesses externalizing symptoms, *Externalizing*, which was used as the primary outcome measure in our study. Internal consistencies for Externalizing were .86, .89, and .86 at ages 2, 3, and 4, respectively, in the current study.

At child ages 2, 3, and 4 assessments, we administered the Eyberg Child Behavior Inventory, a widely used 36-item measure of early childhood problem behavior (Robinson, Eyberg, & Ross, 1980). The Eyberg includes two factors that focus on the perceived intensity of a behavior and degree to which the behavior is a problem for caregivers. Because the Intensity factor is similar in content and structure to the CBCL Externalizing factor, for our study, we focused on the Problem factor, which asks caregivers to use a 7-point scale to report the extent to which the behavior is a problem for the parent. The inventory has been demonstrated to be highly correlated with independent observations of children's behavior, to differentiate clinic-referred and nonclinic populations (Robinson et al., 1980) and to show high test–retest reliability (.86) and internal consistency (.98; Webster-Stratton, 1985). In our study, internal consistencies for the Problem factor were .84, .90, and .94 at ages 2, 3, and 4, respectively.

Procedures

Assessment protocol. Parents (i.e., mothers and, if available, alternative caregivers such as fathers or grandmothers) and children who agreed to participate in the study were scheduled for a 2.5-hr home visit. Each assessment began by introducing children to an assortment of age-appropriate toys and having them play for 15 min while the mothers completed questionnaires. After the free play (15 min), which began with the child being approached by an adult stranger (i.e., undergraduate videographer), each primary caregiver and child participated in a cleanup task (5 min), followed by a delay of gratification task (5 min), four teaching tasks (3 min each, with the last task being completed by alternate caregiver and child), a second free play (4 min), a second cleanup task (4 min), the presentation of two inhibition-inducing toys (2 min each), and a meal preparation and lunch task (20 min). Exactly the same home-visit and observation protocol was repeated at ages 3 and 4 for both the control and the intervention groups. Families received $100 for participating in the age 2 home visit. Families were reimbursed $120 at the age 3 assessment and $140 at the age 4 assessment.

The randomization sequence was computer generated by a staff member who was not involved with recruitment. Randomization was gender balanced to ensure an equal number of males and females in the control and intervention subsamples. To ensure that the randomization was blinded, the examiner opened a sealed envelope, revealing the family's group assignment only after the assessment was completed, and shared this information with the family. Examiners carrying out follow-up assessments were not informed of families' randomly assigned condition.

Relevant to this study, we present maternal reports of child externalizing problems from ages 2, 3, and 4 assessments and direct observations of parent–child interaction from the child ages 2 and 3 assessments. Coding of family assessment videotapes was completed for ages 2 and 3 to test the hypothesis of a link between improvements in positive behavior support in response to the intervention and change in young children's problem behavior.

Coding of videotaped parent–child interactions. A team of undergraduates coded the videotaped family interaction tasks by using the Relationship Process Code (RPC; Jabson, Dishion, Gardner, & Burton, 2004). The average team RPC percent agreement = .87, κ = .86. The RPC is a third-generation code derived from the Family Process Code (Dishion, Gardner, Patterson, Reid, & Thibodeaux, 1983) used extensively in previous research. After coding each family interaction, coders completed a coder impressions inventory regarding proactive and positive behavior support practices, for the purpose of this research study. All family interaction tasks were evaluated in the scoring of positive behavior support practices. In addition, the home visitors' ratings of parent involvement with the young child were used as another indicator of the positive behavior support construct. Although coders were predominantly European American (90%), protocols developed by using examples of culturally diverse coding categories and by extensive training ensured that coding of family interactions was culturally sensitive. Our previous research revealed that cultural biases in coding of African American family interactions existed when coders were untrained in the coding system and that coder training resulted in eliminations of coding differences between European American and African American coders (Yasui & Dishion, 2007).

In detail, the following items were entered into the positive behavior support scores:

1. Parent Involvement. This measure is based on the home visitor's rating of the parents' involvement, which used the following items from the Home Observation for Measurement of the Environment inventory (HOME; Bradley, Corwyn, McAdoo, & Garcia-Coll, 2001): "Parent keeps child in visual range, looks at often"; "Parent talks to child while doing household work"; and "Parent structures child's play periods."
2. Positive Behavior Support. This measure is based on videotape coding (durations) of caregivers prompting and reinforcing young children's positive behavior as captured in the

following RPC codes: positive reinforcement (verbal and physical), prompts and suggestions of positive activities, and positive structure (e.g., providing choices in a request for behavior change).

3. Engaged Parent–Child Interaction Time. This measure reflects the average length of parent–child sequences that involve talking or physical interactions such as turn taking or playing a game. Thus, the average duration of episodes that included consecutive parent–child exchanges involving RPC codes such as Talk and Neutral Physical Contact were used to define these episodes.
4. Proactive Parenting. Videotape coders rated each parent on his or her tendency to anticipate potential problems and to provide prompts or other structural changes to avoid young children becoming upset and/or involved in problem behavior on the following six items: parent gives child choices for behavior change whenever possible; parent communicates to the child in calm, simple, and clear terms; parent gives understandable, age-appropriate reasons for behavior change; parent adjusts/defines the situation to ensure the child's interest, success, and comfort; parent redirects the child to more appropriate behavior if the child is off task or misbehaves; parent uses verbal structuring to make the task manageable ($\alpha = .835$).

Intervention protocol: The FCU. Families randomly assigned to the intervention condition were then scheduled to meet with a parent consultant for two or more sessions, depending on the family's preference. The FCU is a brief, three-session intervention based on motivational interviewing and modeled after the Drinker's Check-Up (Miller & Rollnick, 2002). Typically, the three meetings include an initial contact session, an assessment session, and a feedback session (Dishion & Kavanagh, 2003). However, to optimize the internal validity of the study (i.e., prevent differential drop out for experimental and control conditions), the assessments were completed before random assignment results were known to either the research staff or the family. Thus, for the purpose of research studies only, the sequence of contacts comprised an assessment (baseline), randomization, an initial interview, a feedback session, and possibly follow-up sessions. Families were given a gift certificate for $25 for completing the FCU at the end of the feedback session, which could be used at local supermarkets or video stores.

As described earlier, the initial meeting was an assessment conducted with research staff, during which the family engaged in a variety of in-home videotaped tasks of parent–child interaction and caregivers completed several questionnaires about their own, their child's, and their family's functioning. Also during this home assessment, staff completed ratings of parent involvement with and supervision of their child. The second session was an initial interview by the parent consultant, during which the consultant explored parent concerns, focusing on family issues that were currently the most critical to the child's well-being. The third meeting involved a feedback session, during which the parent consultant summarized the results of the assessment by using motivational interviewing strategies. An essential objective of the feedback session is to explore the parents' willingness to change problematic parenting practices, to support existing parenting strengths, and to identify services appropriate to the family needs. The parents were also offered follow-up sessions that focused on parenting practices, other family management concerns (e.g., coparenting), and contextual issues (e.g., child care resources, marital adjustment, housing, vocational training).

Parent consultants who completed the FCU and follow-up parenting sessions were a combination of Ph.D.- and master's-level service workers, all of whom had previous experience in carrying out family-based interventions but at the study's outset had no experience in using the FCU. The parent consultants were of diverse ethnic status, including Latino, African American, European American (the majority), and mixed ethnicity. The consultants were initially trained for 2.5–3 months by using a combination of strategies, including didactic instruction and role playing, followed by ongoing videotaped supervision of intervention activity. Before working with study families, parent consultants were initially certified by lead parent consultants at each site who had been certified by the intervention developer (Dishion, 1990). Certification was established by reviewing videotapes of feedback and follow-up intervention sessions to evaluate whether the parent consultants were competent in all critical components of the intervention as described later in this article. This process is repeated yearly to reduce drift from the intervention model and adheres to the methods of Forgatch, Patterson, and DeGarmo (2005), which revealed that direct observations of therapist fidelity to parent management training predicted change in parenting practices and child behavior. In addition, cross-site case reviews were convened weekly via videoconference to further enhance fidelity. Finally, annual parent consultant meetings were held to update training, discuss possible changes in the intervention model, and address special intervention issues reflected by the needs of families across sites.

Of the families assigned to the treatment condition, 77.9% participated in the initial interview and feedback sessions at child age 2, and 65.4% participated at child age 3 (see Table 1 for site-specific data). Of those families who met with a parent consultant, the average number of sessions per family was 3.32 (*SD* = 2.84). The number of sessions was uncorrelated with future levels of problem behavior after controlling for initial levels.

Data analysis. We used a variety of strategies to test the hypotheses guiding this research. Latent growth mixture modeling (LGMM) analyses were conducted using Mplus 4.21 (Muthén & Muthén, 2007) to examine heterogeneity in developmental trajectories of early problem behaviors and positive parenting, including possible heterogeneity in intervention response. Three separate sets of analyses were conducted, examining possible heterogeneity in (a) Eyberg Problem Behavior trajectories, (b) CBCL Externalizing behavior trajectories, and (c) change in the Positive Parenting latent variable. Mixture modeling is an active area of methods research regarding the optimal approach to determining the number of latent classes (e.g., Nylund, Asparouhov, & Muthén, 2006). We attempted to obtain fit indices for conditional models with one to six classes at each age. Models with different numbers of latent classes are not nested; therefore, Muthén and Muthén (2000) have recommended the following four criteria for selecting the optimal number of latent classes in factor mixture models: (a) the Bayesian information criterion (BIC) and a sample-size-adjusted version of the BIC (adj. BIC), with lower scores representing better fitting models; (b) the quality of classification across models, represented by entropy, with higher entropy values indicating better classification of individuals into their most likely trajectory class; (c) the Lo–Mendel–Rubin–likelihood ratio test (LMR–LRT) and the bootstrap likelihood ratio test (BLRT), each of which provides a statistical comparison of the fit of a given model with a model of one fewer classes; and (d) the theoretical relevance and usefulness of latent trajectory classes. Recent simulation studies by Nylund et al. (2006) supported the use of adj. BIC and BLRT for selection of the optimal number of classes in latent class analysis models, with the BLRT providing particularly consistent correct results. In light of these findings, primary weight was placed on the BLRT and the adj. BIC values in selecting the number of classes. All analyses were conducted using 100 randomized start values run for 10 iterations each, with the best fitting 25 randomized start values run to model convergence.

Subsequent mediator analyses examined the indirect effect of intervention on the rate of change in problem behaviors through the effect of intervention on maternal positive behavior support at child age 3. The basic mediation model is shown in Figure 3. In the mediation models, the slope of problem behaviors was regressed on age 3 positive behavior support and intervention status, and positive behavior support at child age 3 was regressed on intervention status, the initial level of child problem behaviors, and positive behavior support at child age 2. Thus, this model tests whether intervention is related to the change in positive behavior support from child ages 2 to 3, and whether this change in positive behavior support, in turn, predicts the rate of change in child behavior problems from ages 2 to 4, controlling for the direct effect of intervention. A statistical test of the significance of the indirect effect from intervention to the change in maternal symptoms to the rate of change in problem behavior was examined, with standard errors for indirect effects calculated using the delta method described by MacKinnon and colleagues (MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002; MacKinnon, Lockwood, & Williams, 2004).

Results

Descriptive statistics for all variables are shown in Table 2. For ease of interpretation, we present *t* scores on the Eyberg and CBCL measures, although raw scores were used for models to avoid potential age and gender corrections. The percentage of the respondents in the clinical range on these measures at each age is also presented in Table 2. In terms of validating children's problem behavior status, for both the CBCL Externalizing and the Eyberg Problem Behavior factors, mean scores were approximately 1 *SD* above normative scores at age 2. Using the borderline clinical cutoff of the 90th percentile for the CBCL, 48.6% of children were reported to have clinically elevated scores on the Externalizing factor at age 2. This percentage was reduced over time to 24% at age 4.

Correlations for problem behavior variables from age 2 to 4 and correlations for positive behavior support variables from age 2 to 3 are shown in Table 3. It is important to note that no significant associations were found between treatment group and child gender or ethnicity, levels of maternal depressive symptoms, or any type of child problem

Figure 3. Mediation model overview: Test of indirect path from treatment to age 3 positive behavior support to slope of problem behavior.

behavior at age 2, suggesting that randomization was successful. Modest to moderate associations were consistently found among the observed indicators of positive behavior support. In addition, modest but significant negative associations were found between ethnicity and dimensions of positive behavior support, with African American mothers observed to show lower levels than European American mothers.

The central analyses tested the following hypotheses: (a) that random assignment to a family-centered intervention would result in reductions in the frequency of externalizing problems and those problems being perceived as problematic by mothers, (b) that intervention would also result in improvement in parenting practices, and (c) that reduction in the frequency of externalizing symptoms and those symptoms that were a problem for mothers would be mediated by improvements in parenting. All analyses were conducted using Mplus 4.1 and used full information maximum likelihood estimation (Muthén & Muthén, 2004), which provides a method for accommodating missing data by estimating each parameter by using all available data for the estimation of that specific parameter.

Table 2
Descriptive Statistics

	M	*SD*	Total *N*	*N* (%) in clinical range
Eyberg Problem Behavior (*t* score), age 2	59.18	8.46	729	323 (44.2)
Eyberg Problem Behavior (*t* score), age 3	59.61	10.36	642	321 (43.9)
Eyberg Problem Behavior (*t* score), age 4	59.63	11.01	616	302 (41.3)
CBCL Externalizing behavior (*t* score), age 2	59.49	8.21	730	355 (48.6)

Note. CBCL = Child Behavior Checklist.

Hypothesis 1: Problem Behavior in Early Childhood

For the Eyberg Problem Behavior scale, model fit indices converged to indicate that a two-class LGMM provided optimal fit to the data. Most centrally, both the LMR–LRT and the BLRT were significant for the two-class versus one-class model (LMR–LRT = 51.24, $\Delta df = 11$, $p < .05$; BLRT = 51.24, $\Delta df = 11$, $p < .05$), and the adj. BIC value was lower for the two-class (adj. BIC = 13232.43) versus the one-class model (adj. BIC = 13246.06). Models with three or more classes yielded higher adj. BIC values (three-class adj. BIC = 13239.57) and nonsignificant LMR–LRT and BLRT values (e.g., three-class LMR–LRT = 25.69, $\Delta df = 10$, $p = .20$; BLRT = 25.69, $\Delta df = 10$, $p = .20$).

Entropy for the two-class model was relatively low (.52), indicating that the two classes were not well discriminated. The two classes appeared to be ordered along a severity dimension, with 56% of youth in an elevated-problem class and 44% of youth

in a lower problem class, with the average class trajectories nearly parallel from ages 2 to 4. Membership in the elevated-problem class was predicted by male gender (logit = −.69, *SE* = .29, $p < .05$). In the elevated class, ethnic minority status predicted both the initial level (β = 3.31, *SE* = 1.27, $p < .05$) and the slope of problem behaviors (β = 3.56, *SE* = 1.30, $p < .05$). Intervention status significantly predicted reduced growth in problem behaviors in the elevated-problems class (β = −1.03, *SE* = .44, $p < .05$; B = −.16). In the lower problems class, ethnic minority status predicted reductions in both the initial level (β = −3.43, *SE* = 1.49, $p < .05$) and the slope of problem behaviors (β = −5.67, *SE* = 1.07, $p < .05$). Intervention status was not significantly related to the problem behavior slope, however (estimate = −.27, *SE* = .38, *ns*). Results for intervention effects in these two classes are depicted graphically in Figure 4.

For the CBCL Problem Behavior scale, model fit indices did not support the existence of heterogeneous trajectory classes, indicating that a one-class LGMM provided the best fit to the data. Most centrally, LMR–LRT and BLRT results indicated that a two-class model did not result in significantly improved model fit over a one-class model (LMR–LRT and BLRT = 55.15, *ns*). Thus, we used a one-class model to test the hypothesis that the intervention reduced child behavior problems on the CBCL.

The latent growth model for the externalizing scale from the CBCL provided excellent fit to the data, $\chi^2(df = 3) = 6.01$, $p = .11$; comparative fit index (CFI) = .99; root mean square error of approximation (RMSEA) = .04; standardized root mean residual (SRMR) = .02. The model yielded significant intercept (estimate = 20.63, *SE* = .27) and slope values (estimate = −2.00, *SE* = .22), as well as significant residual variance in the intercept (estimate = 41.57, *SE* = 3.82) and slope parameters (estimate = 11.24, *SE* = 1.79). The effect of intervention on the rate of change in problem behavior was significant (estimate = −.82, *SE* = .29; β = −.12), with more growth in problem behavior in the control group.

An additional series of latent growth models examined possible gender and ethnicity differences in the effect of intervention on the rate of change in problem behavior. First, to examine possible gender differences in the effect of intervention, we examined the fit of a two-group model comparing results for males and females. The difference in the chi-square value across a model with all paths constrained to be equal across genders, and a model allowing the intervention effect to vary by gender was found to be nonsignificant for both the Eyberg Problem Behavior ($\Delta\chi^2$ = 1.60, Δdf = 1, *ns*) and the Externalizing Behavior

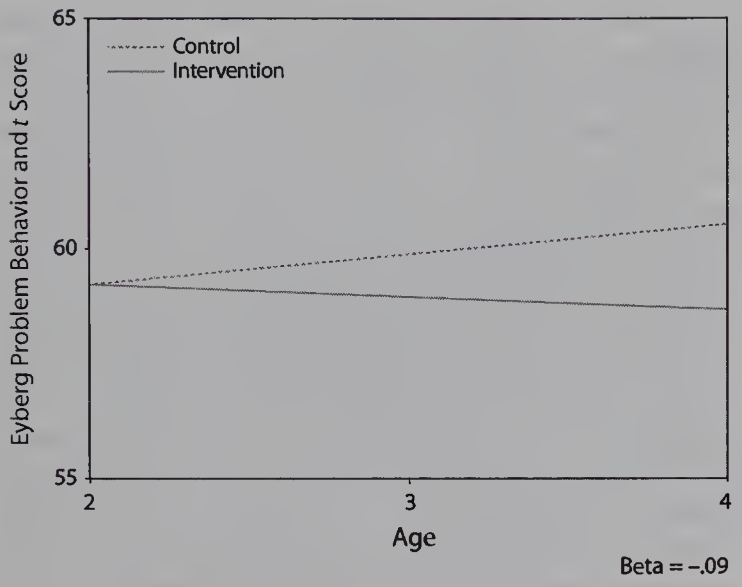

Figure 4. Change from ages 2 through 4 years on the Eyberg measure of child problem behavior (ITT).

Problem scales ($\Delta\chi^2 = 2.21$, $\Delta df = 1$, *ns*), indicating that the intervention effect did not vary by gender.

Second, possible ethnicity differences in the effect of intervention were examined by comparing the fit of models constraining all paths to be equal for European American and ethnic minority families with models allowing the intervention effect to vary across ethnicity groups. The difference in the chi-square value across a model with all paths constrained to be equal across ethnicity groups and a model allowing the intervention effect to vary by ethnicity was found to be nonsignificant for both the Eyberg Problem Behavior ($\Delta\chi^2 = .85$ $\Delta df = 1$, *ns*) and the Externalizing Behavior Problem scales ($\Delta\chi^2 = 2.52$, $\Delta df = 1$, *ns*), indicating that the intervention effect did not vary by ethnicity. In light of the nonsignificant differences in the effects of intervention across either gender or ethnic groups, no further differences in effects across groups were explored.

Hypothesis 2: Observations of Positive Behavior Support Practices

To test Hypothesis 2, we examined the measurement model for the positive behavior support construct, which included the following indicators: (a) home visitor ratings of parent involvement, (b) direct observations of positive behavior support (positive reinforcement, positive prompting, and structuring), (c) direct observation of the engaged parent–child interaction time (parent–child interact time), and (d) coder impressions of proactive parenting.

For the positive parenting latent variable, model fit indices did not support the existence of heterogeneous classes, indicating that a one-class LGMM provided the best fit to the data. Most centrally, LMR–LRT and BLRT results indicated that a two-class model did not result in significantly improved model fit over a one-class model (LMR–LRT and BLRT = 81.20, p = *ns*). Thus, we approached the analysis of the impact of the intervention on positive behavior support by using a one-class, autoregressive model, as shown in Figure 3.

We examined simultaneously the convergent validity of these indicators of parenting and the stability

and the intervention effect, as shown in Figure 5. Factor loadings were constrained to be equal across ages 2 and 3. Figure 5 shows that the four indicators formed a coherent construct and were highly stable from ages 2 to 3 ($\beta = .81$). Despite the high stability, random assignment to the intervention resulted in statistically reliable improvements in observed positive behavior support. The model shown in Figure 3 provides a good fit to the data, $\chi^2(df = 26) = 32.48$, $p = .18$; CFI = .99; RMSEA = .02; SRMR = .04.

Hypothesis 3: Positive Behavior Support and Child Problem Behavior

As indicated, Hypothesis 3 was tested with mediator analyses, examining the indirect effect of intervention on the rate of change in problem behaviors through the effect of intervention on maternal parenting at child age 3. For ease of interpretation, these results are shown in Figures 6 and 7. Because LGMM analyses indicated that there was no heterogeneity in positive behavior support or in CBCL externalizing problems, we tested mediation by using one-class models (i.e., a typical latent variable model including an autoregressive model for positive behavior support and a latent growth model for child behavior problems). As shown in Figure 6, the model for externalizing problem behavior from the CBCL provided reasonable fit to the data by most indices of model fit, $\chi^2(df = 66) = 88.85$, $p = .04$; CFI = .98; RMSEA = .02; SRMR = .04, and the nonsignificant chi-square may be related to the large sample size. In this model, the direct effect of intervention on the problem behavior slope was not significant with maternal parenting included in the model. Treatment significantly predicted improvements in positive behavior support from child ages 2 to 3. More positive behavior support predicted less growth in problem behavior. The indirect effect from intervention to more positive behavior support to decreased growth in problem behavior was statistically significant, although small in magnitude, indicating a significant partial mediation effect of positive behavior support.

Figure 7. Mediation model: Eyberg Child Behavior Inventory.
$^*p < .05$.

As shown in Figure 7, the model for problem behavior from the Eyberg Child Behavior Inventory provided reasonable fit to the data by most indices of model fit, $\chi^2(df = 66) = 89.45$, $p = .03$; CFI = .98; RMSEA = .02; SRMR = .04, and the nonsignificant chi-square may be related to the large sample size. The direct effect of intervention on the problem behavior slope was not significant with positive behavior support in the equation. The family-centered intervention significantly predicted improvements in positive behavior support from child ages 2 to 3. More positive behavior support predicted less growth in problem behavior in early childhood. The indirect effect from intervention to more positive behavior support to less growth in problem behavior was statistically reliable.

Discussion

These data support the hypothesis that a brief, adaptive, and tailored approach to supporting positive behavior support practices can prevent the growth of problem behavior in young children at a critical 2-year period in development (ages 2, 3, and 4 years). Moreover, reduction in growth of early childhood problem behavior was associated with improvement in positive behavior support practices from child ages 2 to 3. The effect sizes for the impact of the intervention were in the small to moderate range ($d = .33$, positive behavior support; $d = .23$, problem behavior) when a one-group intention to treat design analysis was used. Similarly, when a person-centered analysis strategy was used, it was revealed that the intervention effect in child problem behavior was most pronounced among the children who were at highest risk at age 2 and was found to be larger than the effect for the entire sample ($d = .33$).

Three significant points can be considered when evaluating effect sizes in general and those resulting from this study in particular (McCartney & Rosenthal, 2000). First, this is a preventive intervention, and many of the families, although at risk, did not display problem parenting or child behavior and therefore change was not to be expected. The EcoFIT was designed in terms of a health maintenance framework; therefore, continued health is an explicit goal and cannot truly be evaluated until the children are in the next developmental stage, which is school age. Second, it appears that a small to moderate effect size is potentially of some practical significance, if indeed these levels of reduction in problem behavior translate to preventing coercive interaction cycles and escalating patterns of problem behavior that might be expected among the highest risk toddlers (Shaw et al., 2003). In an ongoing study by Shaw and colleagues, indices of parenting assessed at age 2 are being found to predict youth reports of arrest at age 15, for which even modest reductions would be an important outcome (Shaw & Gross, in press). Third, the developmental time span for evaluating the preventive impact of the EcoFIT delivered at this age is truncated, and it is possible that the effect sizes may increase over time, as has been found in several other prevention trials (Connell et al., 2007; DeGarmo, Patterson, & Forgatch, 2004; Ialongo, Poduska, Werthamer, & Kellam, 2001; Olds et al., 1997).

Given these considerations, we propose that the relatively small effect sizes may be of practical significance, although more extensive follow-up of this sample is needed to more formally evaluate this expectation. Given the potential continuity of antisocial behavior over time (Loeber & Dishion, 1983; Olweus, 1979) and the likelihood that early onset leads to multiple forms of problem behavior by adolescence (Dishion & Patterson, 2006), the potential for preventing early-onset and serious problem behavior by adolescents could result in enormous economic savings and benefits to children's lives (Miller, 2004).

It is worth noting that the risk of early-onset antisocial behavior in this sample is considerable. In earlier research, we found that early-onset externalizing problems could be predicted by a combination of maternal depression and active, fearless temperament when children were age 2 (Shaw et al., 2006). We in fact screened the population in this study to include mothers and children with multiple risk factors, including maternal depression and child temperament and behavior problems. Therefore, our ability to effectively engage families, briefly intervene to promote positive behavior support, and reduce growth in problem behavior has three major implications.

First, the EcoFIT model in general and the FCU in particular are promising strategies that can be used as an inexpensive intervention in service settings that involve a large number of families at high risk. The WIC venue is especially suitable because its primary goal is to promote the health of young children ages 0–5. Low-income families in need of nutritional and financial support could also be offered cost-effective parenting services that, for many, could have substantial benefits in the long-term reduction of risk. Although it is certainly true that many of the families would benefit from or require more support than the FCU can provide, the use of assessments to target and focus treatment services significantly reduces the cost of the services and improves the engagement of families at high risk (Dishion & Stormshak, 2007). Communities concerned about promoting the behavioral health of children and ensuring school readiness could use WIC as a venue for empirically supported prevention practices.

Second, this study provides an important addition to a sparse literature on intervention mechanisms (Weersing & Weisz, 2002) by showing that even a brief, individually tailored intervention that typically involves limited opportunity for skills training effectively mediates change in positive behavior support style and skill. Other studies finding this effect have used considerably longer interventions that involved more extensive behavioral skills training (Gardner et al., 2006; Gardner, Hutchings, & Bywater, 2007; Martinez & Forgatch, 2001).

Third, the sample studied was diverse with respect to both gender and ethnicity. As previously stated, a unique advantage of the adaptive, tailored EcoFIT family intervention is that it is flexibly delivered and responsive to a wide variety of families and children. Indeed, we found no significant differences among our study's ethnic groups in terms of engagement or effectiveness of the intervention. Nevertheless, given our experience with diverse families, it is important to consider further improvements in the intervention model's capacity to meet the needs of a wide variety of families. For example, many minority families in the United States deal with challenges such as acculturation stress, discrimination, or simply maintaining cultural strengths and coherence in the face of a dominant, majority community. We are currently developing a broader assessment menu that will enable assessment of the strengths and needs of families of various ethnicities that is relevant to factors such as racial socialization and cultural resilience (Yasui & Dishion, 2007). Presently, however, it is reassuring that the flexibility of the EcoFIT approach and the FCU delivered by a culturally sensitive therapist is helpful to majority and minority families.

This study's findings corroborate results from the broader literature on the effectiveness of preventive interventions aimed at reducing child conduct problems in early childhood among families at high risk

(Baydar, Reid, & Webster-Stratton, 2003; Olds, 2002). The findings also provide additional support for the effectiveness of the FCU in general (Connell et al., 2007; Dishion et al., 2003) and its application to high-risk families during the toddler period. In an earlier study with a smaller sample of toddler-age boys from an urban community, we found that one session of the FCU reduced subsequent child externalizing problems and increased positive behavior support and parental involvement (Gardner et al., 2007; Shaw et al., 2006). The results of our current study suggest that a repeated FCU session engenders more consistent improvements in child behavior and parenting outcomes with a larger and more ethnically diverse sample of boys *and* girls followed from ages 2 to 4.

Finally, the results of this randomized intervention trial provide an important feedback loop to developmental theory. It was originally hypothesized that early support for family management in toddlerhood would reduce the emergence of problem behavior in early childhood. The effect of the intervention based on observations supports three key ideas relevant to developmental psychology. First, early parenting is malleable and responsive to interventions. Concern often arises from longitudinal studies that do not include interventions that associations observed between parenting practices and child behavior are nothing more than genetic effects (e.g., Harris, 1995; Rutter et al., 1997). Our findings suggest that change in parenting practices indeed translates to improved childhood outcomes, as have the findings of other intervention studies that have pointed to a link between changing parenting practices and child and adolescent outcomes (e.g., Dishion, Patterson, & Kavanagh, 1992; Forgatch & DeGarmo, 1999). Second, some change in parenting can result from focusing on caregivers' motivation rather than on direct training, and this was especially true for the highest risk families. This finding suggests a disruption model of poor parenting, in that many parents would engage in more positive parenting practices in the right circumstances but that stress and other family dynamics may disrupt *performance* in childrearing practices (Patterson, 1983). This is an optimistic perspective for developmental and prevention science and for those concerned with improving long-term outcomes for children. Finally, these data suggest that an early focus on positive and proactive parenting practices can prevent the emergence of parent–child coercion dynamics known to be prognostic of more serious antisocial behavior down the line in development. This finding suggests the need to integrate both relational and positive and negative interaction dynamics to further understand the contribution of the caregiving environment in developmental psychopathology.

Limitations

Our study has methodological limitations that merit consideration. First, although we presented evidence to suggest that the FCU is associated with improvements in child problem behavior and positive behavior support, effect sizes, albeit meaningful from a public health perspective, were relatively modest. There are two reasons for the small effect sizes. One, although families in the study were at high risk, many of them were actually doing well when evaluated with standardized measures of child problem behavior and direct observation. Therefore, a change was not expected or induced. Two, we suspect that for those families with more serious difficulties that do not change, two patterns of core issues are basic to the family disruption. One is the caregivers' affective adjustment, usually depression as a function of having several young children under conditions of poverty. We considered the effects of the intervention on maternal depression in another analysis of these data and indeed found reduced levels of maternal depression as a function of the intervention (Shaw, Connell, Dishion, Wilson, & Gardner, 2008). The other is a history of maternal trauma that underlies both the depression and the poverty conditions of the family. Psychosocial interventions such as EcoFIT will have limited impact in some contexts and conditions, and these conditions require attention at the broader level of the community and the nation. Nevertheless, the EcoFIT model can be helpful for some caregivers in affective distress (Shaw et al., 2008), and we plan to further develop this component of the intervention model following principles derived from evidence-based practices that target depression, dissociation, and anxiety secondary to difficult circumstances and history.

A second limitation of the study is that for this age, we had only one reporting agent to address the clinical significance of the child's problem behavior. Because participation in the intervention group might have biased later maternal reports of child behavior, it would have been more optimal to have had a second informant of child behavior. Relevant data will be forthcoming from teachers in the coming years. How well a child adapts to the public school environment is a key test of the overall benefit of early intervention because this critical transition has significant long-term consequences for the child's future and adjustment (Kellam & Van Horn, 1997). Continued follow-up of our study sample will shed light on the endurance of intervention gains seen in the home context and whether such effects are evident at school.

Clearly, many traditional models of mental health intervention are wanting with respect to the most vulnerable families and children. Consistent with insights shared by Kazdin (1987) and others (Dishion & Patterson, 1993; Patterson, Dishion, & Chamberlain, 1993), a health maintenance model is likely more appropriate than a "medical model." That is, continued support helps vulnerable families and children continue to maintain healthy parenting practices and relationship patterns that promote children's adjustment through adolescence and into young adulthood. Thus, we now cast EcoFIT as a health maintenance model designed for implementation in contexts that facilitate regular and repeated exposure and influence on children and families and less for freestanding mental health clinics that do not have ties to institutions such as public schools (see Dishion & Stormshak, 2007).

Our current findings endorse previous evidence that long-term improvements in young children's problem behavior can be achieved with a brief family-based intervention for toddlers. Our study also showed that improving positive behavior support practices mediated positive child behavior change. Reduction in child problem behaviors was achieved using an existing, nationally available service delivery setting for low-income children who are at risk for early-starting pathways of externalizing problem behavior and whose families do not typically use mental health services, especially this early in their child's development. Future follow-up of this study's cohort should clarify questions regarding the intervention's endurance, potential changes in effect sizes, and the benefits of the changes to the child's adaptation to the school environment.

Maternal Socialization of Positive Affect: The Impact of Invalidation on Adolescent Emotion Regulation and Depressive Symptomatology

Marie B. H. Yap and Nicholas B. Allen
ORYGEN Research Centre and University of Melbourne

Cecile D. Ladouceur
University of Pittsburgh

This study examined the relations among maternal socialization of positive affect (PA), adolescent emotion regulation (ER), and adolescent depressive symptoms. Two hundred early adolescents, 11 – 13 years old, provided self-reports of ER strategies and depressive symptomatology; their mothers provided self-reports of socialization responses to adolescent PA. One hundred and sixty-three mother – adolescent dyads participated in 2 interaction tasks. Adolescents whose mothers responded in an invalidating or "dampening" manner toward their PA displayed more emotionally dysregulated behaviors and reported using maladaptive ER strategies more frequently. Adolescents whose mothers dampened their PA more frequently during mother – adolescent interactions, and girls whose mothers reported invalidating their PA, reported more depressive symptoms. Adolescent use of maladaptive ER strategies mediated the association between maternal invalidation of PA and early adolescents' concurrent depressive symptoms.

The ability to successfully regulate affective states is central to mental health, and indeed, it has been noted that emotion dysregulation figures prominently in mental illness (Gross & Munoz, 1995). This may be particularly true of depressive disorders, as they are characterized by deficits of positive affect (PA) and/or an excess of negative affect (NA; Gross & Levenson, 1997). Because depressive disorders involve dysfunction of both the major affective systems (i.e., both aversive and appetitive; P. M. Cole & Kaslow, 1988; Gross & Munoz, 1995), failures or abnormalities in emotion regulation (ER) processes are likely to play a particularly critical role in their etiology.

There is much debate in the field regarding the definition of ER (e.g., P. M. Cole, Martin, & Dennis, 2004), and some researchers assert that ER and emotion generation/reactivity are largely inseparable processes (Campos, Frankel, & Camras, 2004). In this article, we acknowledge the critical, and to some extent unresolved, points raised in this debate and hence conceptualize ER more broadly to incorporate processes of emotional reactivity and its effortful regulation. Specifically, ER refers to the internal and transactional processes through which individuals alter or maintain an affective state, often in the service of accomplishing their prioritized, situation-specific goals (Diamond & Aspinwall, 2003; Gross, 1999). ER can occur at any level of the emotion process, at any time the emotion is activated, and can be evident before an emotion is manifested (Campos et al., 2004). Difficulties with altering an undesirable affective state or maintaining a desirable state will henceforth be referred to as "emotion dysregulation." In particular, dysregulation of NA can involve an individual being (too) easily drawn into a negative affective state (when directly or indirectly provoked), becoming "stuck" in that undesired state (i.e., maintains the NA for longer than desired) and/or using strategies that are ineffective in altering the affect as desired. Likewise, PA dysregulation can involve less frequent PA (e.g., less easily drawn into that desirable state) and an inability to maintain one's positive affective state for a longer duration.

For example, Tomarken and Keener (1998) predicted that depressed individuals should display longer maintenance (i.e., greater "temporal continuity") of NA and poorer ability to maintain PA. Consistent with this prediction, depressed adolescents were found to maintain depressive affective states for a longer duration compared to their nondepressed peers during parent – adolescent interactions (Sheeber, Allen, Davis, & Sorensen, 2000). Relatedly, emerging evidence suggests that emotion dysregulation in at-risk or depressed individuals may be linked to deficits in the strategies they use to

respond to negative emotional states (e.g., Garber, Braafladt, & Weiss, 1995; Garber, Braafladt, & Zeman, 1991). One implication of these findings is that a better understanding of how ER skills develop will be valuable for the design of targeted prevention and early intervention strategies for young people with ER difficulties and at risk for depression, especially given that adolescence constitutes a time of particular risk for the onset of depressive disorders (e.g., Kessler, Avenevoli, & Merikangas, 2001; Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993).

Research indicates that the family caregiving environment plays a crucial role in children's development of ER skills (e.g., Cassidy, 1994; Field, 1994). It has been postulated that caregivers provide "scaffolding" for a child's emotional development (Astington, 1996; Southam-Gerow & Kendall, 2002), and individuals' relationships with their parents set a developmental context for their ER in adolescence and young adulthood (Morris, Silk, Steinberg, Myers, & Robinson, 2007). Evidence suggests that parental behaviors that are low in support and high in conflict are associated with adolescents' regulation of dysphoric affect and experience of depressive symptomatology (e.g., J. P. Allen, Hauser, Eickholt, Bell, & O'Connor, 1994; Sheeber, Hops, Alpert, Davis, & Andrews, 1997; Sheeber, Hops, Andrews, Alpert, & Davis, 1998). Indeed, the family remains a key influence in the child's ER (Sheeber et al., 2000) and mental health (e.g., Gottman, Katz, & Hooven, 1997; Ramsden & Hubbard, 2002) even during adolescence. As Calkins and Bell (1999) have argued, developmental shifts during the transition to adolescence set an important context for parental involvement in the regulation of emotions. To date, however, research on ER during the adolescent period has been largely neglected, particularly in youth at risk of depression (for exceptions, see Kobak, Cole, Ferenz-Gillies, Fleming, & Gamble, 1993; Sheeber et al., 2000; Silk, Steinberg, & Morris, 2003). Moreover, there is evidence that the family remains a vital source of support during adolescence and that family relations have a stronger association with adolescents' depressive symptomatology than peer relations (e.g., Barrera & Garrison-Jones, 1992; McFarlane, Bellissimo, & Norman, 1995). This study aims to examine the role of parental socialization (as one form of family processes) in the development of ER and depressive symptoms in early adolescence.

Parental Socialization of ER

Though the majority of research on emotion socialization has focused on very young children (e.g., P. M. Cole & Kaslow, 1988; Fox, 1994; also see review by Keenan, 2000), preliminary evidence suggests that older children and adolescents may learn to regulate their emotional arousal through parents' responses to their emotional expressions or behavior (e.g., Eisenberg, Fabes, & Murphy, 1996; Eisenberg et al., 1999; Klimes-Dougan et al., 2007).

Research to date on parental responses to child NA indicates that parental socialization characterized by acceptance, coaching, and problem solving are positively associated with children's adaptive responses to NA and inversely associated with depressive symptomatology (Eisenberg et al., 1996; Garber & Dodge, 1991; Gottman, Katz, & Hooven, 1996). Nonetheless, parental socialization of children's PA, and its effect on adolescent emotional functioning and mental health, is still a largely neglected issue in this field. Moreover, research examining the role of parents in emotion socialization after early childhood, especially leading into the adolescence period, has also been scarce, despite this being a critical time for the onset of depression (Kessler et al., 2001).

The pertinence of examining the effects of parental socialization of PA (as distinct from NA) is directly and indirectly implicated by evidence from two fields of research. The first set of evidence comes from the broader parenting literature. Research with young children has demonstrated that parents who frequently discuss emotions (positive and negative), including explanation of the causes and consequences of emotions and reactions to children's expressed emotion, tend to have children with better emotional skills in early childhood (Denham & Kochanoff, 2002; Denham, Mitchell-Copeland, Strandberg, Auerbach, & Blair, 1997; Eisenberg & Fabes, 1994; Halberstadt, Crisp, & Eaton, 1999), which is in turn associated with better ER skills (Fredrickson, 1998; Southam-Gerow & Kendall, 2002). Moreover, parents' positive attentiveness toward their preschoolers' positive and negative affective displays was related to children's emotional and social competence (Denham et al., 1997). However, given the documented changes that occur in the dynamics of parent–child relationships as children approach adolescence (see review by Yap, Allen, & Sheeber, 2007), more research in older childhood and early adolescence is needed. Furthermore, for the purpose of delineating the direct influence of parents on *adolescent ER*, an examination of specific parenting behaviors in response to their adolescent child's behaviors may be more informative. Besides, specific parenting behaviors with adolescents may also be able to inform the focus of interventions for adolescent psychopathology more effectively.

The second set of evidence is presented in a recent review on the relevance of neural systems of PA to the understanding of child and adolescent depression (Forbes & Dahl, 2005). Citing neurobehavioral evidence, namely, in the neural substrates of reward processing, the Forbes and Dahl (2005) distinguish between PA and NA, cogently arguing for the importance of examining the role of PA in youth depression. In particular, the function and interrelation of neural circuits involved in reward processing, including the striatum, orbitofrontal cortex, and amygdala, have specific associations with behavioral manifestations and are indicative of the independence of PA from NA. An important implication of this is the need to examine how children's ability to regulate their positive affective system can be disrupted, and the role of parents (protective or otherwise) in this process.

Of note, although PA is by definition pleasant and desirable, it can be considered inappropriate and/or excessive in certain contexts, especially by parents toward their child. Whether this is due to social norms or expectations, or parental intolerance or poor ER (e.g., in parental depression), parents sometimes respond to child PA in an invalidating manner, by restricting (e.g., instructing child to quiet down), punishing (e.g., reprimand or angry response), or dampening (dysphoric or still-faced response) their child's PA expression. Children who receive such socialization responses to their PA over time may learn to suppress their PA (or at least its expression) and may fail to develop adaptive skills in regulating their PA (Denham et al., 1997). These in turn may contribute to anhedonic tendencies that are purportedly a unique feature of depressive disorders (Clark & Watson, 1991). The overall aim of this study was to investigate whether such invalidating parental socialization of PA is associated with early adolescents' ER and depressive symptoms and whether the socialization–depression association is mediated by adolescent ER.

The Current Study

The assessment design of the current study is multimethod and multisource for measures of parental socialization and adolescent ER, using self-reports as well as observational coding of behaviors during mother–adolescent interactions. We measured early adolescents' ER through the observation of their behaviors in addition to their self-report of ER strategies because observational methods have the potential to capture the dynamics of the ER process and thus contribute unique insights to the understanding of ER compared to methods that focus solely on self-reported ER strategies or affective measures. This study design permits a more comprehensive assessment because each source or method not only provides unique information but also contributes unique error. For example, a sequential observational system permits the detection of microsocial behavioral patterns without the intrusion of perceptual biases inherent in self-report measures, whereas self-report measures provide input from individuals who have substantially greater access than observers to internal regulatory processes and behavior patterns as they occur across time and setting (Sheeber, Davis, Leve, Hops, & Tildesley, 2007). The specific hypotheses for this study were the following:

1. More invalidating (e.g., restrictive, punishing, or dampening) and fewer validating (e.g., encouraging expression) maternal socialization responses to child PA will be associated with higher levels of adolescent depressive symptomatology. Maternal socialization is indicated by maternal self-report and behavioral indices of mothers' responses to their child's PA during mother–adolescent interactions. Given the known associations between parental psychopathology and parenting behaviors (Leinonen, Solantaus, & Punamaki, 2003), maternal depressive and anxiety symptoms were controlled for in all analyses involving maternal socialization.
2. Early adolescents who receive more invalidation and less validation of their PA will display higher levels of emotional dysregulation. Adolescent emotion dysregulation is indicated by greater frequency, duration and reciprocity of negative affective behaviors and lower frequency and duration of positive affective behaviors. It is hypothesized that fewer positive affective behaviors will be reflective of anhedonic tendencies observed in depressed individuals, though this has not been tested empirically to date in adolescents using behavioral observational methodology. Adolescent emotion dysregulation is also indicated by more frequent use of maladaptive ER strategies (as assessed by self-report).
3. Adolescent emotion dysregulation is associated with more depressive symptoms.
4. The relationship between maternal socialization and adolescent depressive symptomatology is mediated by adolescent ER.

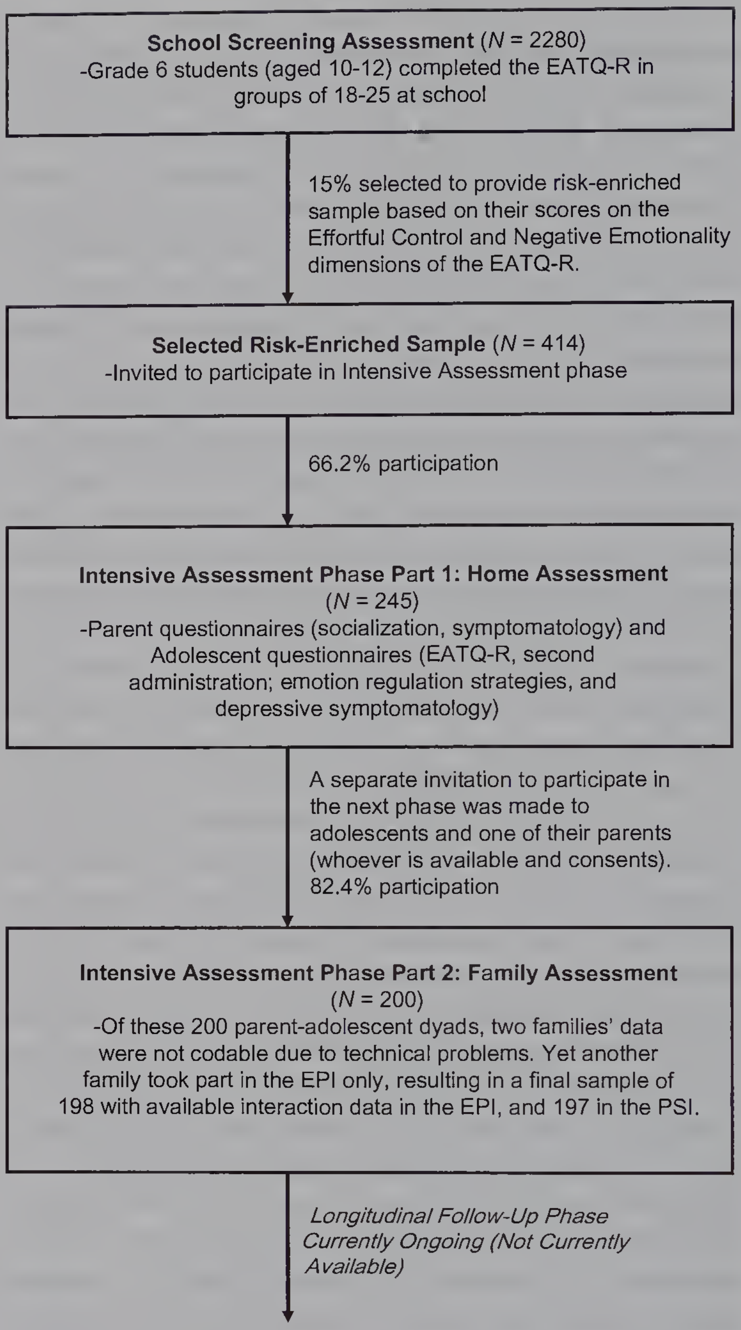
Method

Participants and Selection Procedure

Final-year primary school students across metropolitan Melbourne, Australia, were recruited through their schools to take part in the school screening phase. Through this process, 2,280 students completed Early Adolescent Temperament Questionnaire–Revised (EATQ–R; Ellis & Rothbart, 2001) in the classroom. Given that the main aim of the screening procedure was to provide a risk-enriched sample for the more intensive assessment phase, the EATQ–R scores were used to select a sample that was representative of scores across the full range of the temperament dimensions. Selection was based on scores on Negative Emotionality (NEM) and Effortful Control (EC) dimensions, given their hypothesized role as risk factors for emotional and behavioral disorders. Accordingly, equal numbers of male and female students were selected from each of the following ranges of scores on each dimension: 0–1, 1–2, 2–2.5, and greater than 2.5 *SD* above and below the mean. As outlined in Figure 1, this produced a risk-enriched sample (*N* = 414) for the intensive assessment phase that shows a relatively even distribution across EC and NEM while maintaining the range of temperament scores evident in the larger sample.

The first part of the intensive assessment phase included a battery of questionnaires each for parents and early adolescents to complete. From the selected sample, 245 families consented to participate in this assessment, which occurred a mean of 9.91 months (*SD* = 3.10) after the school screening. At the time of intensive assessment, participating adolescents were 11–13 years old (*M* = 12.46, *SD* = 0.43), and parents' ages ranged from 29 to 57 years (*M* = 42.56, *SD* = 5.19). Although youths of this age range are in their "early adolescence," they are referred to as "adolescents" in this article for ease of expression. Analyses revealed no differences between adolescents who discontinued participation after the school screening phase and those who participated in the intensive phase (Part 1) on NEM, $t(407) = 0.16$, *ns*, or EC, $t(413) = -0.54$, *ns*. The groups also did not differ in gender, $\chi^2(1, N = 415) = 0.34$, *ns*, or socioeconomic classification, $t(405) = -1.00$, *ns*. Socioeconomic classification was based on an index of neighborhood social disadvantage (using participants' residential postal codes), which is calculated as a sum of 13 indicators, such as unemployment, income, criminal offenses, child abuse, and early school leaving (Vinson, 2004).

The 245 families were then invited to take part in the family assessment, and from this, 200 parent–adolescent dyads consented. However, one family completed only the Event-Planning Interaction (EPI), and two sets of data from other participants were not codable. This resulted in 198 sets of behavioral data on the EPI (163 mothers, 80 boys) and 197 (162 mothers, 79 boys) on the Problem-Solving Interaction (PSI). Adolescents who declined to participate in the family assessment did not differ significantly from those who participated in NEM, $t(243) = 0.49$, *ns*; EC, $t(242) = -0.85$, *ns*; gender, $\chi^2(1, N = 245) = 0.15$, *ns*; or mother's country of birth (by continental regions), $\chi^2(7, N = 245) = 12.03$, *ns*. Of the 198 adolescents, 50% were female, and 92% self-identified as "Australian." This sample also did not differ from the original sample (*N* = 2,280) in gender, $\chi^2(1, N = 2,261) = 0.50$, *ns*; or socioeconomic classification, $t(2,241) = 1.55$, *ns*.



School Screening Assessment (*N* = 2280)
-Grade 6 students (aged 10-12) completed the EATQ-R in groups of 18-25 at school

15% selected to provide risk-enriched sample based on their scores on the Effortful Control and Negative Emotionality dimensions of the EATQ-R.

Selected Risk-Enriched Sample (*N* = 414)
-Invited to participate in Intensive Assessment phase

66.2% participation

Intensive Assessment Phase Part 1: Home Assessment
(*N* = 245)
-Parent questionnaires (socialization, symptomatology) and Adolescent questionnaires (EATQ-R, second administration; emotion regulation strategies, and depressive symptomatology)

A separate invitation to participate in the next phase was made to adolescents and one of their parents (whoever is available and consents). 82.4% participation

Intensive Assessment Phase Part 2: Family Assessment
(*N* = 200)
-Of these 200 parent-adolescent dyads, two families' data were not codable due to technical problems. Yet another family took part in the EPI only, resulting in a final sample of 198 with available interaction data in the EPI, and 197 in the PSI.

Longitudinal Follow-Up Phase Currently Ongoing (Not Currently Available)

Figure 1. Sample selection process.
EATQ–R = Early Adolescent Temperament Questionnaire–Revised; EPI = Event-Planning Interaction; PSI = Problem-Solving Interaction.

Given that the sample size of fathers is much smaller than that of mothers, and the exploration of differences in adolescent ER and symptomatology according to parent gender is beyond the scope of this article, all analyses include only the subsample of families where *mothers* participated in the family assessment.

Procedure of Family Assessment Phase

Parents and adolescents participated in two 20-min family interactions, the EPI followed by the PSI (in that fixed order), which were videotaped for coding purposes. Separate cameras videotaped each participant. Order of interactions was fixed because we believed that it would be easier for participants to switch from a positive affective state (as elicited by the EPI) to a conflictual affective state (as elicited by the PSI), given that negative affective states are known to have slower decay rates than positive affective states (Gilboa, 1994). Topics for the EPI and PSI were identified based on participant responses to the Pleasant Events Checklist (PEC) and the Issues Checklist (IC), respectively. The PEC comprises 50 activities that people may enjoy doing, such as "taking a trip or vacation" and "snow skiing," whereas the IC is a list of 44 topics about which adolescents and parents may disagree, such as "[adolescent] lying" and "[adolescent] talking back to parents." Up to 5 activities that both parent and child indicated to be very pleasant in the PEC were chosen for parent–child dyads to plan for during the EPI, and up to 5 topics that were reportedly most conflictual (and recent) on the IC were chosen for the dyads to attempt to resolve during the PSI. As reported in a previous article on this data set (Yap, Allen, O'Shea, et al., 2007), participants displayed more PA in the EPI and more NA in the PSI, indicating a significant task effect. Participants were given $50 cash (parents) and a $30 voucher (adolescents) as reimbursement for their time and travel.

Measures

Parents' Reaction to Children's Positive Emotions Scale

The Parents' Reaction to Children's Positive Emotions Scale (PRCPS; Ladouceur, Reid, & Jacques, 2002) consists of a series of 12 vignettes in which children are likely to experience positive emotions such as joy, pride, excitement, and curiosity. Five of the 12 vignettes have been adapted from the original version (targeted for 4- to 8-year-olds) to be used with older school-age children. The new vignettes were adapted by following the same methodology used to create the original PRCPS for younger children—a committee of experts in developmental psychology and parents (Ladouceur et al., 2002). The PRCPS includes different contexts (with peers or acquaintances, at a birthday party, in a car, etc.), but the parent is always present. Examples of the vignettes used are provided in Appendix A. For each situation, parents indicate on a 7-point scale (from 1 = *very unlikely* to 7 = *very likely*) how likely they would be to react as described in each of the six alternative responses. The PRCPS yields four subscales: Socialization (α = .65), reflecting the degree to which parents explain to their child the reasons why their expressive behavior may be inappropriate given social norms or etiquette; Encouragement (α = .72), indicating the degree to which parents encourage their child to express PA or validate their child's positive emotional states; Reprimand (α = .77), reflecting the degree to which parents react by reprimanding their child for expressing PA; and Discomfort (α = .75), indicating the degree to which parents feel discomfort, embarrassed, or irritated when their child expresses PA. Test–retest reliability of these subscales with preschool children has been reported to range from .60 (Discomfort) to .79 (Reprimand). The convergent/divergent validity of the PRCPS has also been established by significant correlations between its subscales and the scales of other socialization and family environment questionnaires including the Coping with Children's Negative Emotions Scale (Fabes, Eisenberg, & Bernzweig, 1990) and the Family Environment Questionnaire (Moos & Moos, 1981).

For the purpose of data reduction, correlational analyses were conducted to explore whether any of the scales can be collapsed to comprise composite constructs (Appendix A). Analyses revealed that Encouragement was negatively correlated with the other three scales (*r*s = −.27 to −.49); therefore, it is termed *validating socialization,* reflecting nonrestrictive responses to child positive affective displays. The three remaining scales were positively correlated with one another (*r*s = .34 to .66), reflecting parental discomfort and restrictive, dampening responses to child PA. The mean of these scales was calculated and used as an overall index of invalidating socialization of PA, which has a high internal consistency of α = .86.

Child Affect Questionnaire–Child Strategies

The Child Affect Questionnaire–Child Strategies (Garber et al., 1995) was used to assess the frequency with which adolescents engaged in various responses for regulating NA in an interpersonal scenario. Adolescents were instructed to "imagine that you had just had a big fight with a good friend" and to indicate how often they would use each of the strategies after the event, from 1 (*none of the time*), 2 (*a little of the time*), 3 (*about half of the time*), or 4 (*a lot of the time*). The strategies were grouped into six categories based on the existing literature concerning categories of affect regulation and coping strategies (e.g., Band & Weisz, 1988). However, only the Negative Responses scale was used in this study as a measure of "maladaptive ER" strategies, as this scale is conceptually and empirically indicative of poor ER (e.g., N. B. Allen, Sheeber, Leve, Davis, & Golston, 2003). The Negative Responses scale consisted of nine strategies, including "talk back to parents" and "continue to argue with the friend," and had a high Cronbach's alpha of .80. These strategies reflect deficits in managing the NA experienced in the given conflict scenario, resulting in inappropriate venting and dysregulated expressions of NA. Although almost 18% of adolescents reported using these strategies "none of the time," 71% of them reported using at least some of these strategies "a little of the time" (*M* = 13.47, *SD* = 4.34).

Center for Epidemiological Studies Depression Scale – Revised

Maternal and adolescent depressive symptomatology was measured using self-reports on the Center for Epidemiological Studies Depression Scale – Revised (CES-D – R; Radloff, 1977). The CES-D – R has been found to be valid and reliable for adults and adolescents, with Cronbach's alpha of .85 reported in both a general population sample of adults (Radloff, 1977) and a nonclinical sample of junior high school students (Radloff, 1991). Most of this adolescent sample reported few depressive symptoms (*M* = 11.44, *SD* = 9.38), with 59% having total scores of 0 – 10. Approximately 11% (14 male and 11 female) had total scores of 24 and above, suggesting that they have a relatively high likelihood of meeting criteria for major depressive disorder (Roberts, Lewinsohn, & Seeley, 1991). Many mothers also reported few depressive symptoms (*M* = 10.37, *SD* = 10.09), with 62% having total scores ≤ 10, although 19% reported total scores exceeding the adult clinical cutoff of 16. Cronbach's alphas were .89 and .92 for adolescents and parents, respectively, in this study.

Beck's Anxiety Inventory

A state measure of maternal anxiety symptoms was obtained by maternal self-report on the Beck's Anxiety Inventory (BAI; Beck & Steer, 1990). The BAI has demonstrated good psychometric properties in a nonclinical college sample, showing a high internal consistency with Cronbach's alpha of .90, which is comparable to that in this sample (α = .92). Using the guidelines of Beck and Steer (1990) for score ranges, 70% of mothers reported a "normal" anxiety level, 23% mild to moderate, 3% moderate to severe, and 4% severe anxiety.

Family Observation Measure

The affect and verbal content of the videotaped interactions were coded in real time using the Living in Family Environments (LIFE; Hops, Davis, & Longoria, 1995) coding system. The LIFE is an event-based coding system in which new codes are entered each time the affect or verbal content of the interactants changes. The LIFE consists of 10 affect codes and 27 verbal content codes. Three composite variables, derived from the individual affect and content codes, were used in the current study (see Appendix B for the full list of codes and composition of constructs). *Aversive* behavior includes all codes with contemptuous, angry, and belligerent affect, as well as disapproving, threatening, or argumentative statements with neutral affect. *Dysphoric* behavior consists of all codes with dysphoric, anxious, or whining affect, as well as complaints and self-derogatory comments with neutral affect. A new Positive Interpersonal behavioral construct was developed for this study, consisting of statements made with happy, pleasant, and caring affect, as well as approving or affirming statements, and statements that serve to maintain the conversation. The validity of the former two constructs has been established in earlier studies examining parent – child interactions (e.g., Hops, Sherman, & Biglan, 1990; Sheeber et al., 2000). More detailed information about the development and psychometric characteristics of LIFE is presented in Hops et al. (1995).

All video recordings were coded by extensively trained observers who are blind to participant characteristics (e.g., temperament or symptomatology levels). Approximately 20% of the interactions were coded by a second observer to provide an estimate of observer agreement. Kappa scores in this study, which were in the good to excellent range (Fleiss, 1981), averaged .66 and .78 for content and affect codes, respectively, and kappa coefficients were .77, .68, and .89 for the Aversive, Dysphoric, and Positive Interpersonal composite codes, respectively. Random pairs of observers were assigned to the interactions to minimize drift between any two observers and to ensure that all observers met minimal criteria for acceptable observations. The base rate for coding an affect or content code was 1, which means that when it fails to occur at least once, it arises as a missing value for that code for that particular participant. This results in variations in *N* for different constructs in different tasks.

On the basis of data obtained from the LIFE coding of family interactions, behavioral indices of maternal socialization and adolescent ER were derived. These include the following.

Rate per minute (rpm). The rpm variable indicates the number of times behaviors associated with a composite construct occurs per minute of interaction between participants. Separate variables were constructed to assess the average frequency of Aversive, Dysphoric, and Positive Interpersonal displays. More frequent aversive and dysphoric behaviors and less frequent positive interpersonal behaviors are taken as indicative of emotion dysregulation. The rpm variable has been more commonly used as a measure of positivity, negativity, and problem-solving capacity in family and parent–child interactions (e.g., Forgatch, 1989; Jacob & Johnson, 2001) and broadly reflects the emotional climate in these relationships. In this study, rpm is used as a broad measure of ER in that it indexes how easily one is drawn into a particular affective state (emotion generation/reactivity), as well as one's capacity in resisting the particular affective state (ER) and hence not produce it as often.

Sequential z score. The *z* scores for sequential relations indicate the extent to which a specified sequence of behavior occurs more or less often than would be expected as a function of the base rate of each behavior. The *z* scores represent whether a particular antecedent behavior is effective in eliciting/increasing the likelihood of (positive *z* score) or suppressing (negative *z* score) a particular consequent behavior (see Hops et al., 1995, for a more detailed description).

Specific behavioral sequences are of interest in this study as indicators of adolescent ER. In particular, greater reciprocity of aversive and dysphoric behaviors (e.g., positive *z* scores of adolescent aversive responses to maternal aversive behavior) is taken as indicative of emotion dysregulation. In creating these variables, antecedent behaviors are regarded as provocative affective stimuli. The extent to which the respondent reciprocates NA is therefore considered to be an index of the respondent's ability to regulate (e.g., diffuse) the affect generated by negative antecedent behaviors. This methodology is consistent with the manner in which difficulties in ER have been assessed in the context of both conflictual marital exchanges (e.g., Lindahl & Markman, 1990) and problem-solving interactions between adolescents (depressed and nondepressed groups) and their mothers (Sheeber et al., 2000).

Invalidating maternal socialization is indexed by a greater likelihood (i.e., more positive *z* scores) of "punishing" (aversive) and "dampening" (dysphoric) maternal responses following adolescent positive interpersonal behavior. Given that there has been minimal research on socialization of PA in adolescents, the punishing and dampening parental response variables were created as a conceptual parallel to maladaptive socialization of NA described in the theoretical and empirical literature (e.g., Eisenberg, Cumberland, & Spinrad, 1998; Eisenberg et al., 1996), which is characterized by punitive, dismissive parental responses to child affect.

Duration per episode (dpe). Dpe represents the average length of time that specific affective behaviors are maintained each time they are displayed during the course of each mother–adolescent interaction task. It is developed to capture the person's ability to shift out of negative affective states as well as to maintain positive states. Separate variables were constructed to assess the average duration of aversive, dysphoric, and positive interpersonal displays. A longer duration of aversive and dysphoric behaviors and a shorter duration of positive interpersonal behaviors are taken as indicative of emotion dysregulation.

To make analyses more methodologically stringent when using maternal behavior variables (as indices of maternal socialization) to predict adolescent behavior variables (as indices of adolescent ER), mother and child behavioral indices are derived from separate interaction tasks. In particular, given our interest in maternal socialization in the normal family environment, as a reflection of the type of parenting the child is usually exposed to, we examine maternal socialization during the nonconflictual, positive affective interaction context (EPI). Moreover, the EPI is more likely to evoke more PA from the adolescent, and it provides more opportunity to examine mothers' socialization responses to such. On the other hand, given our interest in adolescents' ability to regulate their emotions specifically in conflictual contexts (parent–child and/or peer), we examine adolescent ER during the PSI, which presumably poses challenges to the adolescents' ER capacity. In addition, adolescent ER in interpersonal conflictual contexts is also of interest because difficulties in interpersonal relationships have been associated with adolescent depression (Eisenberg et al., 1996, 1998). However, when predictor and outcome variables are derived from different methods (e.g., parent-report socialization or adolescent-report ER strategies with behavioral variables), behaviors in both tasks will be examined.

Results

Given the ample evidence from the developmental literature indicating adolescent gender differences in ER and depressive symptomatology (e.g., Hankin et al., 1998; Thayer, Rossy, Ruiz-Padial, & Johnsen, 2003) and in sensitivity to parental psychopathology and disturbances in parent–child interactions (e.g., Chaplin, Cole, & Zahn-Waxler, 2005; Klimes-Dougan et al., 2007), any moderating effects of gender on the associations between maternal socialization and adolescent outcomes are examined when testing the hypotheses of this study. Because few prior studies have investigated socialization and ER behaviors during parent–adolescent interaction tasks designed to elicit PA, behaviors in the EPI and PSI are examined separately to see if different forms of socialization and emotion dysregulation are evident in different parent–adolescent interaction contexts. All hypotheses were tested using hierarchical regressions, with statistical significance set at $\alpha = .05$. To test the first two hypotheses, adolescent gender was entered in Step 1, maternal depressive and anxiety symptoms in Step 2, maternal socialization in Step 3, and Socialization × Gender interaction in Step 4. To test Hypothesis 3, analyses involved Steps 1, 3, and 4 given above and the predictor variable is adolescent ER. When testing the effect of adolescent ER (mediator) on symptomatology, maternal socialization (predictor) was controlled for as well.

Following the recommendation of Baron and Kenny (1986), the mediation model requires three criterion relationships, namely, (1) predictor (maternal socialization) variable exerts significant effects on mediator (adolescent ER), (2) outcome variable (depressive symptoms), and (3) mediator exerts significant effects on outcome variable. As such, where any of these three relationships was not significant in any model, mediation effects will not be tested. Although some scholars have more recently argued that Criterion (2) should not be required for mediation (MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002), we chose to set these criteria because the conceptual model being tested in this study (Yap, Allen, & Sheeber, 2007) would only be meaningful if these relationships are significant. The significance of any mediation effect will be tested using the Sobel test (Aroian version; Preacher & Leonardelli, 2001), and indirect or mediated effects are calculated following the recommendations of MacKinnon and Warsi (1995). This calculation involves a two-stage regression procedure: First, the mediator (adolescent ER) is regressed on the predictor (maternal socialization). Second, adolescent symptomatology is regressed on both predictor and mediator variables. The product of the regression coefficient of the predictor from the first regression with the coefficient of the mediator in the second regression yields the mediated effect of maternal socialization on adolescent symptomatology.

Adolescent gender had no significant main effects on their ER or depressive symptoms. Maternal symptomatology also had no main effect on adolescent symptomatology, but maternal depressive symptoms were positively associated with adolescent reciprocity of aversive behaviors during the PSI, $\beta = .22$, $t(155) = 200$, $p < .05$, $\Delta R^2 = .04$. All analyses are summarized in Tables 1 and 2.

Predicting Adolescent Depressive Symptomatology With Maternal Socialization

Regression analyses were first conducted to test the associations that adolescent depressive symptomatology has with mothers' socialization responses to adolescent PA. As predicted, maternal dampening of adolescent positive behaviors (i.e., a positive conditional probability for maternal dysphoric behavior given adolescent PA) during both interaction tasks was associated with more symptomatology. Adolescent gender moderated the association between maternal dampening in the EPI and adolescent symptoms, and follow-up analyses revealed that this association was significant for females but not for males, $\beta = .37$, $t(72) = 3.31$, $p < .005$, $\Delta R^2 = .13$. Gender moderation was also found for the association between maternal self-report of invalidating socialization and adolescent symptoms, with the association being significant for females only, $\beta = .32$, $t(75) = 2.97$, $p < .005$, $\Delta R^2 = .10$. Maternal punishing responses during mother–adolescent interactions and maternal report of validating socialization of PA were unrelated to adolescent depressive symptomatology.

Predicting Adolescent ER With Maternal Socialization

Consistent with expectations, adolescents whose mothers report being prohibitive of their PA displays (invalidating socialization) were more likely to reciprocate their mothers' aversive behaviors. Validating socialization was not directly associated with adolescent ER behaviors, but adolescent gender moderated some of these associations, which were significant for males but not for females. Male adolescents whose mothers report being more likely to encourage their positive affective displays demonstrated better ER during the PSI. These boys behaved aversively less often, $\beta = -.30$, $t(72) = -2.65$, $p < .01$, $\Delta R^2 = .08$; maintained their positive behaviors for a longer

Table 1

Summary of Hierarchical Regressions Predicting Adolescent Depressive Symptomatology With Maternal Socialization and Adolescent Emotion Regulation Variables

	N	B	$SE\ B$	β	ΔR^2
Maternal socialization responses to Ad positive affect					
Mo aversive given Ad positive (EPI)	148	0.36	0.63	.05	.00
Mo dysphoric given Ad positive (EPI)	150	2.49	0.85	.24†	.06

Mo aversive given Ad positive (PSI)	151	0.57	0.49	.10	.00
Mo dysphoric given Ad positive (PSI)	149	2.31	0.81	.23†	.05
Mo self-report validating responses (PRCPS)	155	−0.07	0.07	.08	.00
Mo self-report invalidating responses (PRCPS)	155	0.15	0.09	.14	.02
Mo Self-Report Invalidating Responses × Gender		−0.50	0.18	−.31**	.05
Ad ER behaviors (PSI)					
Aversive reciprocity	151	0.51	0.24	.17**	.03
Aversive Reciprocity × Gender		−1.08	0.47	−.27	.03
Dysphoric reciprocity	149	0.49	0.56	.07	.01
Ad ER strategies (self-report)					
Maladaptive ER strategies	134	1.23	0.15	.57††	.33

Notes. These values are based on models controlling for Ad gender (Step 1) and maternal symptomatology (Step 2; no significant main effects and thus not shown here), the above-mentioned variables in Step 3, and the interaction between gender and these variables in the final step (only significant interactions are shown here). The analyses using the frequency and duration of Ad behaviors in both tasks and Ad reciprocity in the EPI as predictors are nonsignificant and hence are not shown here (due to space constraints). A total of 21 regression analyses were conducted. ΔR^2 refers to change in R^2 values from Steps 2 to 3, except where interaction effects are shown, where the change is from Steps 3 to 4. Ad = adolescent; EPI = Event-Planning Interaction; ER = emotion regulation; Mo = mother; Positive = positive interpersonal; PRCPS = Parents' Reaction to Children's Positive Emotions Scale; PSI = Problem-Solving Interaction.
$^{*}p < .05$. $^{**}p < .01$. $^{\dagger}p < .005$. $^{\dagger\dagger}p < .001$.

duration, $\beta = .30$, $t(72) = 2.65$, $p < .01$, $\Delta R^2 = .09$; and were less likely to reciprocate their mothers' aversive behaviors, $\beta = -.30$, $t(72) = -2.82$, $p < .01$, $\Delta R^2 = .09$.

As predicted, adolescents whose mothers were more likely to punish their positive behaviors in the EPI displayed aversive behaviors more often in the PSI. Some gender effects were also found among these adolescents: Males maintained their aversive behaviors for a longer duration, $\beta = .33$, $t(68) = 2.94$, $p < .005$, $\Delta R^2 = .11$, and females were more likely to reciprocate their mothers' dysphoric behaviors, $\beta = .30$, $t(77) = 2.74$, $p < .01$, $\Delta R^2 = .09$. Maternal dampening of adolescent positive behaviors was unrelated to adolescent ER behaviors, and adolescent PA regulation was unrelated to all measures of invalidating maternal socialization.

Adolescents whose mothers reported more invalidating socialization reported using maladaptive ER strategies more frequently. This association was moderated by adolescent gender, and follow-up analyses revealed that it was significant for females only, $\beta = .44$, $t(65) = 4.00$, $p < .001$, $\Delta R^2 = .19$. Adolescents whose mothers were more likely to dampen their positive behaviors during the PSI also reported using maladaptive ER strategies more often. Maternal punishing of adolescent positive behaviors was not associated with adolescent ER strategies.

Predicting Adolescent Depressive Symptomatology With Adolescent Emotion Dysregulation

Contrary to expectations, the frequency (rpm) and duration (dpe) of adolescent Aversive, Dysphoric, and Positive Interpersonal behaviors in both the EPI and the PSI were all not significantly associated with depressive symptomatology. However, adolescents with more depressive symptoms are more likely to reciprocate their mothers' aversive behavior in the PSI and their mothers' dysphoric behavior in the EPI. Moreover, adolescent gender moderated the former association, and follow-up analyses revealed that it was significant for females only, $\beta = .33$, $t(74) = 3.01$, $p < .005$, $\Delta R^2 = .11$. More depressed adolescents also reported using maladaptive ER strategies more frequently when they experience NA.

Testing for Mediation

Following the recommendations of Baron and Kenny (1986), the only potential mediator to be tested here is maladaptive ER strategies, in the associations that maternal dampening behaviors in the PSI, and for females only, maternal report of invalidating socialization, have with adolescent depressive symptomatology because these are the only sets of associations that fulfill all three criteria.

Table 2

Summary of Hierarchical Regressions Predicting Adolescent Emotion Regulation With Maternal Socialization Variables

DV: Ad ER	*N*	*B*	*SE B*	β	ΔR^2

Maladaptive ER Strategies × Gender		−0.22	0.09	−.27*	.04

Notes. These values are based on models controlling for Ad gender (Step 1; no significant main effects and thus not shown here) and maternal symptomatology (Step 2; only one significant main effect, described in text), the above-mentioned variables in Step 3, and the interaction between gender and these variables in Step 4 (only significant interactions are shown here). ΔR^2 refers to change in R^2 values from Steps 2–3, except where interaction effects are shown, where the change is from Steps 3 to 4. Because most analyses involving Ad dysphoric behaviors and maternal socialization in the EPI yielded nonsignificant findings, only those with significant results are shown. A total of 38 regression analyses were conducted. Ad = adolescent; dpe = duration per episode; DV = dependent variable; EPI = Event-Planning Interaction; ER = emotion regulation; IV = independent variable; Mo = mother; Positive = positive interpersonal; PRCPS = Parents' Reaction to Children's Positive Emotions Scale; PSI = Problem-Solving Interaction.
*$p < .05$. **$p < .01$. †$p < .005$. ††$p < .001$.

A series of hierarchical regressions revealed that maladaptive ER strategies accounted for unique variance in symptomatology even after each of the two above-mentioned predictors was entered into the regression model; therefore, the Sobel test was conducted to test for the significance of the mediation effects. As shown in Figure 2, the effects of both socialization variables on adolescent symptomatology became nonsignificant after accounting for the effects of adolescent ER strategies, indicating a significant mediation effect in both cases.

Discussion

On the whole, all four hypotheses were at least partially supported. Maternal dampening of adolescent positive affective behaviors, and in females only, maternal report of invalidating PA socialization, were associated with more adolescent depressive symptoms. Adolescents whose mothers were more likely to punish and dampen their positive affective behaviors during mother–adolescent interactions and to report using invalidating socialization of their PA expression demonstrated more emotion dysregulation.

Moreover, adolescents with more dysregulated behaviors and who use maladaptive strategies more frequently to manage their NA reported more depressive symptoms. Adolescent ER strategies, but not behaviors, significantly mediated the association between maternal invalidation of PA and adolescent depressive symptomatology. Interestingly, validating socialization of PA was related to adolescent ER in males only and was not associated with adolescent depressive symptoms.

Maternal Socialization of PA and Adolescent Depressive Symptomatology

Findings from multimethod, multiinformant measures of maternal socialization partially supported the first hypothesis that invalidating maternal PA socialization predicts more adolescent self-reported depressive symptomatology. However, validating socialization was found to be unrelated to symptomatology. The finding that maternal dampening responses to adolescent positive affective behaviors, as well as maternal report of invalidating PA socialization, are associated with elevated depressive symptomatology in early adolescents extends and replicates findings of recent, unpublished studies (Katz, 2002; Sheeber & Davis, 2002, as described and cited in Sheeber, Allen, Davis, & Katz, 2004). In particular, it is noteworthy that negative socialization of PA has implications for adolescent mental health.

Maternal dampening of adolescent positive behaviors seems to be an important form of maladaptive socialization that warrants further study because most studies of socialization have focused on punishing forms of parental socialization responses. The association between maternal dysphoric responses to their children's positive behaviors resembles those of depressed mothers (e.g., Hops et al., 1990; Jacob & Johnson, 1997); therefore, it may be argued that these mothers' tendency to dampen their adolescents' positive affective displays is related to the mothers' heightened symptomatology. However, our findings demonstrate that maternal socialization has effects on adolescent ER and depressive symptoms over and above any main effects of maternal symptomatology, which were minimal. Further post hoc analyses conducted to examine whether such maternal socialization responses are related to mothers' ER also revealed no significant associations. Therefore, it seems that mothers' likelihood to respond in a dysphoric manner to their adolescents' positive interpersonal behaviors has less to do with the mothers' own emotional functioning than it does with the interpersonal interaction context and the adolescents' emotional functioning.

Maternal invalidating socialization of adolescent PA (including maternal discomfort toward and tendency to use reprimanding or socializing emotion management strategies to decrease their child's expression of PA) was significantly associated with adolescent symptomatology, but only in females. Given that the effect of PA socialization on adolescent depressive symptomatology has not been studied before in past research, it is unclear why no significant effect was found in this study for males, and why maternal punishing behaviors were unrelated to adolescent symptoms as well. It is possible that such socialization behaviors contribute to adolescent depressive symptomatology indirectly via their impact on adolescent ER, namely, increasing the likelihood that these adolescents would reciprocate their mothers' aversive and dysphoric behaviors and use maladaptive ER strategies more often. Invalidating PA Socialization may also have an impact on boys that was not captured by the outcomes examined in this study, for example, on externalizing problems. Likewise, maternal punishing socialization may contribute directly or indirectly to externalizing problems. Nonetheless, in the absence of the replication of these findings, it is difficult to draw firm conclusions.

Maternal Socialization of PA and Adolescent ER

On the whole, as predicted, more maternal invalidation and less validation of adolescent PA, as measured by multimethod, multisource methods, was found to be associated with poorer ER in the adolescent. The associations underscore the impor tance of investigating the previously neglected research area of the socialization of *positive* emotions for a better understanding of the effects of socialization on adolescent ER. Maternal responses that are restrictive and unaccepting of positive affective displays in their children (mother-report invalidating socialization) are associated with a greater likelihood of adolescents reciprocating their mothers' aversive behaviors in the PSI and more frequent use of ineffective ER strategies to manage NA elicited from a peer conflict situation. These findings are consistent with those of Denham et al. (1997), whereby parents' use of guiding and socializing language (similar to PRCPS Socialization and Reprimand scales) was negatively associated with preschool children's emotional and social competence, suggesting that parents may discourage affective displays of children who most actively need such tutelage (i.e., who are seemingly less able to self-regulate). Nonetheless, it is important to note that these cross-sectional associations may differ from longitudinal associations; hence, future research is warranted. Being more easily pulled into aversive exchanges with their mothers is a marker of poor ER for adolescents, given that it suggests an inability to downregulate their aversive affective reaction when provoked by maternal aversive behavior, in this case in a conflict resolution interaction with their mother. Indeed, these adolescents may have a tendency to use maladaptive strategies like venting and dysregulated expression of NA in such conflict situations, whether it is with their mother or their peers.

It is noteworthy that validating PA socialization was associated with better ER in males but not in females. Post hoc analyses revealed that this gender difference was not due to differences in mothers' likelihood to encourage PA expression in girls versus boys. Given the lack of past research into the role of PA validation in adolescent ER, or gender differences in this association, more research is required before further inferences can be drawn. Nonetheless, it is interesting that mothers' validation of their sons' PA is associated with male adolescents' regulation of both positive and negative affective behaviors during a conflict resolution interaction with their mothers. This is broadly consistent with evidence that parental sharing of PA with young children is associated with children's social competence (Denham, 1997). If replicated, these findings have important implications for parenting interventions, suggesting that teaching parents to encourage their sons' PA expression may contribute to their sons' development of better ER.

This study used two behavioral measures of invalidating PA socialization that parallel the mother-report invalidating socialization measure, namely, maternal punishing (aversive) and dampening (dysphoric) responses to adolescent positive interpersonal behaviors. On the whole, the associations that these behavioral measures of socialization have with multimethod, multiinformant indices of adolescent ER are consistent with those involving questionnaire measures of socialization—maternal invalidation of adolescent positive affective displays engender risk for adolescent emotion dysregulation.

Adolescents whose mothers were more likely to respond aversively toward them when they displayed positive interpersonal behavior during the EPI (a context where such behaviors are normative and adaptive, thus making maternal punishing responses somewhat unjustified) displayed aversive behaviors more frequently during the PSI. Amongst these adolescents, males also maintained their aversive behaviors for a longer duration, whereas females were more likely to reciprocate their mothers' dysphoric behaviors. Maternal dampening of adolescent positive interpersonal behaviors was not related to adolescent ER *behaviors* but was associated with adolescents using maladaptive strategies more frequently to manage their NA.

In sum, findings from multimethod, multiinformant measures of maternal socialization of PA and adolescent ER paint a coherent picture consistent with past research involving NA and younger children (e.g., Denham et al., 1997) and with theoretical expectations involving PA. Maternal invalidation of adolescent PA comprises dysfunctional socialization in that they engender risk for adolescent dysregulation of both PA and NA. In particular, this study is among the first to investigate and demonstrate the effects of parental socialization of PA on adolescent ER.

Adolescent ER and Depressive Symptomatology

Adolescents with more depressive symptoms were more likely to reciprocate their mothers' aversive behaviors during the PSI and dysphoric behaviors during the EPI. Such individual differences in aversive and dysphoric reciprocity during early adolescence may be indicators of risk for depressive disorders later in adolescence, arguably because such exchanges underlie poor ER in these early adolescents (Sheeber et al., 2000). In addition, adolescents who use maladaptive, dysregulated expressions and avoidance behaviors more frequently as strategies for regulating their negative emotions presented with elevated depressive symptoms. This latter finding is consistent with research on the ER strategies of adolescents and young adults (e.g., Gross & John, 2003; Silk et al., 2003).

Adolescent ER as a Mediator

Consistent with hypothesis, maternal dampening of adolescent PA predicted adolescent symptomatology through its effects on adolescent ER strategies but not on ER behaviors. This may be because self-report of strategies better reflects trait-like aspects of adolescent ER and is better placed to capture those aspects of adolescent functioning that are consistent over time and are therefore able to mediate the influence of parenting on symptoms. In females only, adolescent ER strategies also mediated the association between mother-report invalidating socialization and depressive symptoms. It is notable, moreover, that the effect of socialization on symptoms dropped to nonsignificance after adding the mediator to the model, suggesting that maladaptive ER strategies are a potent mediator in the association between maternal PA socialization and adolescent depressive symptomatology.

In particular, mothers who respond in an anxious or dysphoric manner (dampening) to their adolescent's positive interpersonal behaviors during the EPI may confer greater risk for depressive symptomatology in these adolescents because they use ineffective strategies more frequently to cope with their NA. The same applies for female adolescents whose mothers express discomfort, socialize, and/or reprimand them for expressing PA (invalidating socialization). In essence, such unjustified discouragement and dampening of their positive interpersonal behaviors may leave these adolescents frustrated and angry yet unable to successfully downregulate these emotions; hence, they experience a buildup of such emotions that can become pervasive and in turn lead to the elevation of depressive symptoms. Alternatively, when frustrated and angry, these adolescents may be less able to upregulate their PA to offset their NA or to diffuse the tension in the parent – adolescent relationship, which in turn contributes to their risk for developing more severe depressive problems.

Gender Differences

Some interesting gender differences emerged in this study, particularly in the associations between maternal PA socialization and adolescent ER and depressive symptoms. Overall, it appears that female adolescents' risk for depression is particularly sensitive to the effects of maternal invalidation of their PA. Researchers have suggested that this may be due to the intensity of the mother – daughter relationship in particular (Youniss & Ketterlinus, 1987) and due to increasing societal demands on them to maintain cordial interpersonal relationships (Davies & Windle, 1997). Notably, these findings suggest that this vulnerability may be evident from early adolescence. An implication of these findings is that parents should be cautious when responding to their daughters' PA even within apparent socialization norms, as such restrictive responses to girls' PA may have adverse effects on their emotional and psychological functioning. On the other hand, boys seem to benefit from maternal validation of their PA expressions, particularly in terms of their ability to regulate both their PA and NA. Hence, although boys are adversely affected by maternal invalidation, these findings suggest that maternal validation may serve as a protective factor for male early adolescents.

Strengths and Limitations

The current study has a number of notable strengths. It is based on a large population sample of adolescents, from which a smaller risk-enriched subsample was selected to represent a wide variance in temperament. Moreover, this study used a multimethod and multisource measure of ER, including a behavioral measure of adolescent ER and a self-report measure of ER strategies. This allowed the examination of multiple dimensions of emotions: valence (PA and NA), frequency, duration, and reciprocity, as recently recommended by researchers in the field (Gross & John, 2003; Larsen, 2000). Furthermore, this study addressed an important gap in the literature by examining the direct effects of maternal socialization of PA on ER and depressive symptoms in early adolescents. It also derived indices of maternal socialization and adolescent ER behaviors from separate interaction tasks and used multimethod and multisource measures of maternal socialization.

There were also limitations to this study. Only mothers were included in this study; hence, the potential differences in the effects of parental socialization due to parent gender could not be examined. The associations reported here are cross-sectional;

thus, findings from the longitudinal follow-up are required to clarify the direction of associations and to examine the possibility that ER mediates the association between parental socialization of PA and depression later in adolescence. In particular, longitudinal data are required to make more rigorous inferences about the causal relations implied in this mediational model (D. A. Cole & Maxwell, 2003). In addition, the risk-enriched sampling design of this study may have inflated effect sizes relative to a normal community sample.

Conclusions

Maternal socialization of adolescent PA has important implications for adolescents' ER strategies and their affective behaviors during mother–adolescent interactions, as well as their concurrent depressive symptoms. Adolescents with more depressive symptoms tend to use maladaptive ER strategies more frequently and display more emotion dysregulation during mother–adolescent interactions. Mothers' invalidation of adolescent PA and adolescents' emotionally dysregulated behaviors are likely to create and contribute to a family emotional climate that limits the adaptive development of ER skills in adolescents and heightens their risk for more severe depressive problems. These findings, albeit preliminary, highlight the importance of focusing on PA when working with parents of young adolescents at risk for depression. For example, parents should be made aware of the impact that preventing their children from experiencing or expressing PA can have on their children's development of ER and their risk for affective problems. It remains to be seen if adolescent ER behaviors would mediate the longitudinal association between their mothers' socialization behaviors and their diagnostic status, namely, of major depression, later in adolescence.

Appendix A: Parents' Reaction to Children's Positive Emotions Scale

Table A1

Intercorrelations Among Subscales of the Parents' Reaction to Children's Positive Emotions Scale

	Discomfort	Encouragement	Reprimand
Socialization	.38	−.25	.50
Discomfort		−.37	.65
Encouragement			−.46

Notes. N = 233, except the right-most column, where *N* = 232. All correlations are significant, *ps* < .001.

Examples of vignettes used (subscale are indicated in parentheses) are the following:

1. If we are sitting on the patio at our friends' house and, while playing with other children, my child is running, jumping and screaming, I would:
    (a) tell my child to calm down and suggest another game that he/she could play (Socialization)
    (b) tell my child, in a firm voice, to stop jumping and running around immediately (Reprimand)
    (c) let my child play and have fun (Encouragement)
    (d) be slightly embarrassed by my child's behavior (Discomfort).
2. If we are going on a family car-trip and, during the two-hour drive, my child and his/her friend are singing and laughing loudly, I would:
    (a) feel annoyed by my child's behavior (Discomfort)
    (b) allow my child to have fun with his/her friend (Encouragement)
    (c) firmly tell my child to stop it right now (Reprimand)
    (d) suggest a quiet game for them to play (Socialization).

Appendix B: Components of Living in Family Environments Constructs

Content codes	Meaning	Affect codes	Meaning
10	Validation	0	Contempt
14	Affection	1	Anger
15	Solicitous	2	Anxious
16	Humor	3	Dysphoric

Infants' Use of Lexical-Category-to-Meaning Links in Object Individuation

D. Geoffrey Hall, Kathleen Corrigall, Mijke Rhemtulla,
Eleanor Donegan, and Fei Xu
University of British Columbia

Infants watched an experimenter retrieve a stuffed animal from an opaque box and then return it. This happened twice, consistent with either 1 animal appearing on 2 occasions or 2 identical-looking animals each appearing once. The experimenter labeled each object appearance with a different novel label. After infants retrieved 1 object from the box, their subsequent search behavior was recorded. Twenty-month-olds, but not 16-month-olds, searched significantly longer for a second object inside the box when the labels were both proper names than when they were 1 count noun followed by 1 proper name. The effect was not significant when proper names were replaced by adjectives. Twenty-month-olds' understanding of meaning distinctions among several word categories guided their object individuation.

By around 2 years, infants have learned that words from different lexical categories in their native language convey distinct types of meaning. Specifically, they have acquired the knowledge that novel words (e.g., "FEP") modeled linguistically as count nouns (e.g., "This is a FEP") label object categories, but those presented as members of other lexical categories carry different semantic implications. For example, infants of this age have discovered that words modeled as adjectives (e.g., "This is very FEP") designate object properties (e.g., Booth & Waxman, 2003; Waxman, 1999; Waxman & Booth, 2001; Waxman & Markow, 1998), words modeled as verbs (e.g., "This is FEPing") mark action categories (e.g., Echols & Marti, 2004), words modeled as prepositions (e.g., "This is FEP my box") label spatial locations (e.g., Fisher, Klingler, & Song, 2006), and words modeled as proper names (e.g., "His name is FEP") refer to individual objects (e.g., Bélanger & Hall, 2006; Hall, Lee, & Bélanger, 2001).

Knowledge of lexical-category-to-meaning links gives infants a valuable tool for constraining the interpretation of novel words. As a result, it significantly influences categorization behavior in a variety of word extension tasks. For example, in a study of infants' understanding of the distinction between count nouns and proper names, Bélanger and Hall (2006) taught infants a novel label for a stuffed animal. One group heard the word modeled as a count noun (e.g., "He is called a DAX"), and another group heard the same word modeled as a proper name (e.g., "He is called DAX"). The animal was then moved to a new location in front of the infant, and a second same-looking animal was placed in the first animal's original location. Infants were asked to look at one of the two objects as a referent of the novel word, modeled either as a count noun (e.g., "Find a DAX") or as a proper name (e.g., "Find DAX"). At 16 months, infants' looking patterns were unaffected by the word's lexical category. At 20 months, however, infants looked first to the labeled animal significantly more often after hearing a proper name than after hearing a count noun (Bélanger & Hall, 2006; for further evidence, see Bélanger & Hall, 2008; Hall et al., 2001; Liittschwager & Markman, 1993; Sorrentino, 2001; Sorrentino & Halberda, 2001). By 20 months, infants thus appeared to have learned lexical-category-to-meaning links for proper names and count nouns in their language, and this knowledge guided their interpretation of novel words.

Another fundamental task facing infants during conceptual development is object individuation. How do infants make appropriate decisions regarding the number of distinct objects present in a scene? Recent research suggests that labeling can influence these judgments. For example, Xu, Cote, and Baker (2005) presented 12-month-old infants with an opaque box

into which they could reach but not see. In the two-word condition, the experimenter looked into the box and said, "Look, a FEP! Look, a WUG!" In the one-word condition, she said, "Look, a ZAV! Look, a ZAV!" After they retrieved one object from inside the box, infants were allowed to reach again. The duration of this second search was the dependent measure of interest, and because the box was empty, search time was interpreted as reflecting the strength of infants' expectation that the box contained two objects. Xu et al. found that 12-month-olds searched significantly longer in the two-word than in the one-word condition, suggesting that after hearing two different count nouns, infants inferred that two objects were hidden in the box. The finding also offers evidence that infants at this age expect that two different count nouns should not apply to one object, perhaps an early manifestation of the assumption of mutual exclusivity (Markman, 1989).

The previous work by Xu et al. (2005) focused on the effect of hearing count noun labels on object individuation among infants who have not yet acquired knowledge of multiple lexical-category-to-meaning links in their language. In the current research, we investigated labeling effects among older infants who have learned at least some of these links. We used a modified version of Xu et al.'s task (cf. Feigenson & Carey, 2003; Van de Walle, Carey, & Prevor, 2000; Xu & Baker, 2005) to explore whether these older infants can use their understanding of the distinct semantic implications of count nouns and proper names to individuate objects.

In our task, we first administered training trials on which infants saw that an opaque box could contain either one or two identical-looking stuffed animals. Infants then took part in two test trials. On each test trial, the experimenter showed infants a new opaque box, retrieved a stuffed animal from inside it and then placed the animal back inside. The experimenter then repeated these actions, retrieving the same animal from inside the box and returning it. Because the two animal appearances looked identical, the event was ambiguous: It could have involved the same animal being shown twice or two different but identical-looking animals, each being shown once. As a result, it was possible to infer either that there was one animal or that there were two distinct but same-looking animals inside the box. Each time she retrieved the animal, the experimenter labeled it with a different novel word. On one test trial, infants heard a different proper name for each appearance of the animal (e.g., "His name is FEP"; "His name is BLICK"), and on the other trial, they heard a count noun followed by a proper name for the two appearances of a stuffed animal of a different kind (e.g., "He is a MUV"; "His name is PRAZ"). On each test trial, the experimenter then invited infants to search for what was inside the box. After retrieving the sole stuffed animal that was inside, infants were allowed to search again. As in Xu et al. (2005), our dependent measure was the duration of this second search, interpreted as a reflection of how strongly infants expected that the box contained two objects.

A test trial in our task had several distinctive features. To begin, it differed from a test trial in Xu et al.'s (2005) task in three primary ways. First, the experimenter showed an object to accompany each novel word, unlike Xu et al.'s task, in which the experimenter simply looked into the box when providing the labels. Second, the experimenter provided a different novel label for each object emergence, unlike Xu et al.'s task, in which the experimenter provided different novel words on one trial but repeated a single novel word on the other. Third, the experimenter varied the lexical category of these labels, unlike Xu et al.'s task, in which the experimenter presented all words as count nouns. Note also that infants in our task could not use spatiotemporal information to resolve the ambiguity surrounding the number of objects present in the box because they saw only one object appearance at a time. Similarly, they could not use property or kind information because the two object appearances had the same properties and were of the same kind. Infants could, however, potentially resolve the ambiguity by using the lexical category information accompanying each object appearance. The linguistic information differed between test trials, and for this reason, we interpreted differences in the duration of the second search on the two trials as reflecting infants' use of these lexical category cues to disambiguate the event.

If infants understand that novel count nouns designate object categories, whereas proper names mark individual objects, we expected that they would individuate the event differently on the two test trials. On the two proper names trial, we predicted that they would infer the presence of two stuffed animals inside the box (i.e., an animal named FEP and another same-looking animal named BLICK) because they would judge two proper names for one object to be a violation of the contrast principle (i.e., different words have different meanings; see Clark, 1993). If both words referred to the same object, they would both provide a name for the same individual object, in violation of the principle. As a result, we expected that infants would reject this possibility (see Hall & Graham, 1999). On the count noun – proper name trial, however, we anticipated that infants would be more likely to infer that the box contained only one object (i.e., an animal that was a MUV, whose name was PRAZ) because they would judge that one count noun and one proper name for one object would not violate contrast (i.e., the two words would have different meanings, one an object category term and the other a name for the individual object). As a result, we expected that they would allow the possibility that this pair of words applied to the same object. After they retrieved the single object inside the box, we thus expected that infants would search more persistently (i.e., longer) on the two proper names trial than on the count noun–proper name trial.

In Study 1, we tested 20-month-olds using sentences that contained multiple cues to distinguish proper names from count nouns. We expected that these infants would know the semantic distinction between count nouns and proper names (cf. Bélanger & Hall, 2006) and, as a result, would individuate the event differently on the two trials. Study 2 was a modified replication of Study 1, in which the sentences containing the novel words held fewer cues to distinguish between count nouns and proper names. Study 3 was a replication of Study 1 with 16-month-olds. We predicted that they would not individuate the event differently on the two trials (cf. Bélanger & Hall, 2006). Studies 4 and 5 examined the basis for 20-month-olds' success on our task. Together, the studies provide the first assessment in the literature of whether infants' nascent understanding of distinct lexical-category-to-meaning links guides them in the fundamental task of object individuation.

Study 1

Method

Participants. Participants were 16 infants (8 girls and 8 boys), with an average age of 20.3 months (range = 18.5–22.5 months). We also tested, but excluded from the final sample, 5 infants for failing to complete the task, and 1 for having a search time longer than 2.5 *SD* from the mean on at least one trial. In this study and subsequent studies, all infants were acquiring English as their native language, and most were from middle- or upper-middle-class Caucasian families. Infants were recruited from a database maintained by a developmental research group in a university psychology department. Infants received a T-shirt and a certificate for participating; parents were reimbursed for parking or transit expenses.

Materials. On training trials, we used one stuffed dog and two identical stuffed monkeys. On test trials, we used one stuffed bear and one stuffed rabbit. All were between 12 and 18 cm in their longest dimension.

We also used one opaque box on training trials (44 × 30 × 21 cm) and two others on test trials (29 × 25 × 21 cm and 29 × 25 × 23 cm). Each had an opening on one side (roughly 17 × 10 cm), covered in fabric strips. As a result, infants could reach but not see inside.

The study was conducted at a table in a playroom of a developmental laboratory in a university psychology department. The experimenter sat at a 90° angle to the infant on the infant's left side. The infant sat either in a booster chair or on her parent's lap. A digital video camera recorded the infant's search behavior and was placed so that it faced the experimenter and captured the infant's right side profile.

Design and procedure. All infants took part in two training trials followed by two test trials.

Training trials. The purpose of the training trials was to ensure that infants understood that a box could contain either one or two stuffed animals, and to give them experience in reaching inside. On the first trial, the experimenter placed the empty training box on the table in front of the infant, put the stuffed dog inside, and asked the infant, "Can you get what's inside?" If the infant did so, the experimenter offered praise, took the toy, and thanked her. Keeping the stuffed dog in the infant's view, the experimenter pushed the box back toward her and asked, "Do you think there's anything else inside the box?" The infant then received a second opportunity to search. Regardless of the infant's response, the experimenter took the box after 10 s, shook it, and said, "It's empty!"

The second trial was similar to the first, except that the experimenter placed the two identical-looking stuffed monkeys inside the empty training box. If the infant retrieved one toy on each of the two reach opportunities, the experimenter offered praise, took the toy, and thanked the infant each time. If the infant retrieved both toys on the first reach opportunity, the experimenter offered praise, took the toys, and thanked the infant.

On either training trial, if the infant failed to retrieve a toy that was still inside the box, the experimenter provided assistance by pulling a small part of the object through the opening. Any infant who still failed to retrieve a toy on either training trial was excluded from the study.

Proper name–proper name (PN-PN) test trial. The experimenter placed one of the two test boxes on the table. The box already contained either the stuffed bear or the stuffed rabbit. The experimenter reached into the box, pulled out the toy, and repeated a novel proper name five times. She said, "Look! His name is

FEP! Do you see FEP? I think FEP wants to come see you! Do you want to play with FEP?" The infant was allowed to play with the toy for approximately 10 s. The experimenter then took back the toy and thanked the infant. The experimenter said, "I'm going to put FEP back inside the box!" and placed the toy back inside.

The experimenter then reached back into the box and repeated the procedure, using a second proper name, "BLICK."

Count noun–proper name (CN-PN) test trial. The experimenter placed the other test box on the table. It already contained the stuffed animal not used on the PN-PN trial. The procedure was the same as on the PN-PN trial except that the experimenter presented the first novel word as a count noun. The experimenter said, "Look! He is a MUV! Do you see the MUV? I think the MUV wants to come see you! Do you want to play with the MUV?" Following the 10-s play period, the experimenter said, "I'm going to put the MUV back inside the box!"

The experimenter then reached back into the box and repeated the procedure using a second word, "PRAZ," introduced as a proper name, exactly as on the PN-PN trial.

Note that the only linguistic difference between test trials was in the sentence frames used to introduce the first novel word. On the PN-PN trial, the first sentence frame containing the first novel word (a proper name) was "His name is ___," and the novel word in the four subsequent sentence frames had no determiner. On the CN-PN trial, the first sentence frame containing the first novel word (a count noun) was "He is a ___," and the determiner, "the," preceded the novel word in the four subsequent sentence frames.

On both test trials, the experimenter then pushed the box toward the infant, with the covered opening in front of the infant and asked, "Can you get what's inside the box?" The infant was required to retrieve the single animal inside. If the infant did not do so, the experimenter provided assistance by pulling a small part of the object through the opening. Any infant who still failed to retrieve the toy was excluded from the study. After retrieving the toy, the infant was allowed to play with it for approximately 10 s.

The experimenter then took the toy back, placed it in the infant's view, pushed the box back toward the infant, and gave the infant a second opportunity to search inside. The duration of this second search was our dependent variable. It is important to note that there was never a second object in the box on test trials. It is also important to note that infants never received any encouragement or assistance on this second search opportunity. If infants did not initiate a search within 10 s, the trial ended.

We counterbalanced between participants both the order of the two test trials (PN-PN and CN-PN) and the order in which we presented the two kinds of toys (bear and rabbit), ensuring that each kind of toy was used half the time on each type of test trial. We also counterbalanced between participants the order in which we presented the two words associated with each animal (i.e., FEP and BLICK for the bear; "MUV" and "PRAZ" for the rabbit).

Data analysis. A primary coder, blind to trial order and trial type, coded the videotapes frame by frame for the duration of infants' second search. As in previous research using this paradigm (Van de Walle et al., 2000; Xu et al., 2005), we considered an infant to be searching inside the box when the knuckles that join the fingers to the hand were inside the box's opening. A second coder, also blind to trial order and trial type, subsequently recoded the data. Intercoder agreement was calculated to be $r = .99$. Trials on which there was a disagreement of 0.5 s or more between coders were reviewed by both coders together, discussed, and subsequently retimed by the primary coder.

Results and Discussion

As predicted, 20-month-olds searched longer on the PN-PN trial than on the CN-PN trial. We conducted a 2 × 2 mixed analysis of variance (ANOVA) on the search duration data, with trial order (PN-PN first, CN-PN first) as the between-subjects factor and trial type (PN-PN, CN-PN) as the within-subjects factor. The only significant effect was that for trial type, $F(1, 14) = 10.73$, $p = .006$, partial $\eta^2 = .434$ (Figure 1). In addition, 12 of the 16 infants' second

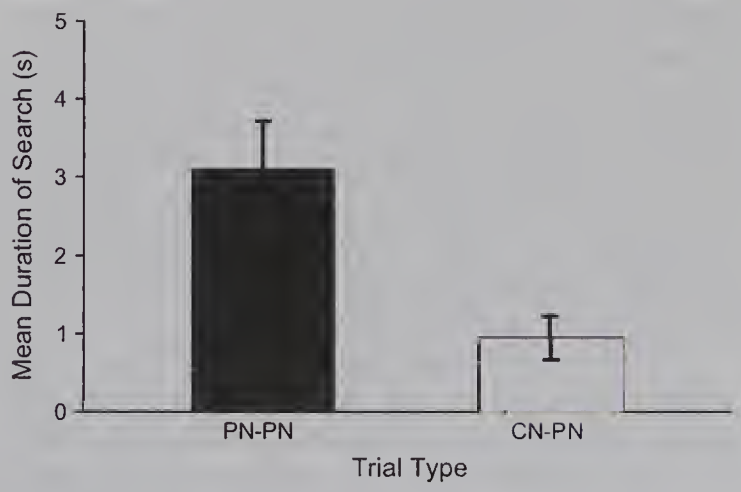

Figure 1. Results of Study 1.
Note. Bars represent 1 *SE*. PN = proper name; CN = count noun.

searches were longer on the PN-PN trial than on the CN-PN trial, $p = .038$ (one tailed) by a sign test.

Twenty-month-olds searched more persistently for a second stuffed animal inside a box after observing two appearances of the same animal labeled with different proper names than after observing them labeled with a count noun followed by a proper name. The result suggests that 20-month-olds distinguished between proper names and count nouns, and it indicates that they were more likely to expect two objects to be in the box after hearing two proper names than after hearing the combination of a count noun followed by a proper name. The finding also suggests that infants' nascent knowledge of the semantics of different lexical categories guided their object individuation.

The results are consistent with the claim that 20-month-olds understand that proper names label individual objects, whereas count nouns label object categories. The findings also suggest that infants have knowledge of conditions under which two novel words should pick out two objects, such as when the words would violate the contrast principle if they referred to the same object (Clark, 1993). If infants understand these lexical-category-to-meaning links and honor contrast, then we would expect them to reject two proper names for the same object because the two words would have the same meaning (i.e., they would both refer to the same individual object). We would not, however, expect infants to reject the combination of one count noun followed by one proper name for one object because this word combination would not violate contrast (i.e., the words would have different meanings; one would refer to an object category, whereas the other would refer to an individual object; see Clark, 1993; see also Diesendruck, 2005; Hall & Graham, 1999).

We note that our interest was in determining whether there were *any* circumstances under which infants would distinguish a trial involving two proper names (i.e., a PN-PN trial) from a trial involving one count noun and one proper name. We obtained our positive evidence using a trial on which the count noun *preceded* the proper name (i.e., a CN-PN trial). We make no claim about 20-month-olds' ability to distinguish a PN-PN trial from a PN-CN trial, although we have no a priori reason to expect that they would be unable to do so.

In Study 1, infants received multiple linguistic cues to help them distinguish proper names from count nouns. The sentences containing the first mention of the terms differed by three words (i.e., "His name is ___" vs. "He is a ___"). The sentences containing the subsequent four mentions of the word differed in terms of the absence or presence of the determiner, "the." However, recent research (Bélanger & Hall, 2006, 2008) has found evidence that 20-month-olds can distinguish semantically between proper names and count nouns, given only the presence or absence of the determiner as a cue. In Study 2, we sought to replicate the results of Study 1, giving infants only this minimal cue.

Study 2

Method

Participants. Participants were 16 infants (7 girls and 9 boys), with an average age of 20.7 months (range = 19.0–22.3 months). None had taken part in Study 1. We also tested, but excluded from the final sample, 1 infant for failing to complete the task and 2 for having a search time longer than 2.5 *SD* from the mean on at least one trial.

Materials. These were the same as in Study 1.

Design and procedure. These were the same as in Study 1 except that the sentence frames containing the first mention of the proper name and the count noun now differed only in terms of the presence or absence of a determiner ("a" or "the") before the novel word. Proper names were first introduced in the sentence, "This is ___", and count nouns were introduced in the frame, "This is a ___." Note that this change in wording makes the task of identifying the proper names more challenging because the frame, "This is ___," leaves open the possibility that the novel word is a proper name (e.g., "This is John"), an adjective (e.g., "This is pink"), or a mass noun (e.g., "This is fur"). As a result, infants in Study 2 needed to rely on the subsequent four sentences to establish unambiguously that the novel word was a proper name (e.g., "I think X wants to come see you" is felicitous only if "X" is a proper name).

Data analysis. Coding was carried out as in Study 1. Intercoder agreement was calculated to be $r = .95$.

Results and Discussion

As in Study 1, 20-month-olds searched longer on the PN-PN trial than on the CN-PN trial. We conducted the same ANOVA as in Study 1. The only significant effect was that for trial type, $F(1, 14) = 5.28$, $p = .038$, partial $\eta^2 = .274$ (Figure 2). Unlike Study 1, however, only 10 of the 16 infants' second reaches were longer on the PN-PN trial than on the CN-PN trial, nonsignificant by a sign test.

As in Study 1, 20-month-olds appeared to distinguish between proper names and count nouns, and the findings again suggest that infants were more

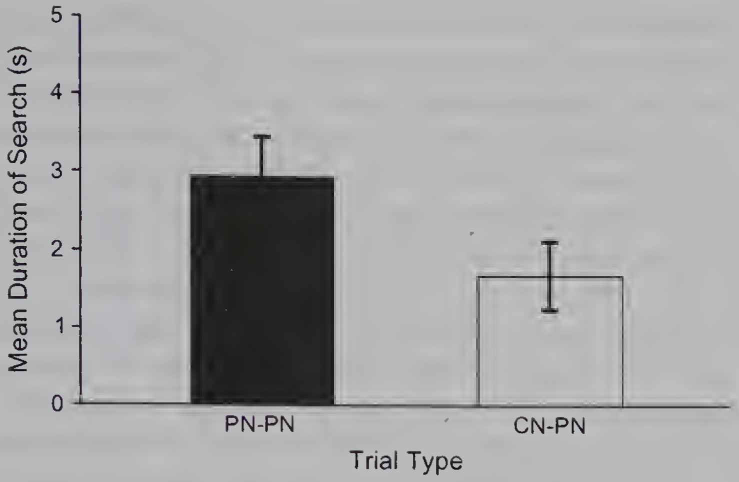

Figure 2. Results of Study 2.
Note. Bars represent 1 *SE*. PN = proper name; CN = count noun.

likely to expect two objects in the box after hearing two proper names than after hearing the combination of a count noun followed by a proper name. However, the trial type effect size was smaller in this study (partial $\eta^2 = .274$) than it was in Study 1 (partial $\eta^2 = .434$), as was the number of infants searching longer on the PN-PN trial (10 in Study 2 vs. 12 in Study 1). This difference between studies suggests that infants' ability to distinguish between the two lexical categories was weaker when they received only the presence or absence of a determiner as a cue to the distinction.

To analyze the effect of the number of linguistic cues on the effect of trial type, we combined the data from Studies 1 and 2 and conducted a 2 × 2 × 2 mixed ANOVA, with number of cues (multiple in Study 1 and minimal in Study 2) and trial order (PN-PN first, CN-PN first) as between-subjects factors, and trial type (PN-PN, CN-PN) as a within-subjects factor. There were no interactions involving number of cues, suggesting that despite any apparent differences between the results of the two studies, 20-month-olds distinguished comparably between proper names and count nouns in both.

Study 3 was an attempt to replicate the results of Study 1 with 16-month-olds. In previous research, children of this age have failed to distinguish between proper names and count nouns in a categorization task involving word extension (Bélanger & Hall, 2006; see also Bélanger & Hall, 2008). As a result, we predicted that 16-month-olds would search equivalently on the two test trials of our individuation task.

Study 3

Method

Participants. Participants were 16 infants (8 girls and 8 boys), with an average age of 16.5 months (range = 15.4 – 17.8 months). We also tested, but excluded from the final sample, 7 infants for failing to complete the task and 1 for having a search time longer than 2.5 *SD* from the mean on at least one trial.

Materials. These were the same as in Study 1.

Design and procedure. These were the same as in Study 1.

Data analysis. Coding was carried out as in Study 1. Intercoder agreement was calculated to be $r = 1.0$.

Results and Discussion

Unlike Study 1, 16-month-olds did not search significantly longer on the PN-PN trial than on the CN-PN trial. We conducted the same ANOVA as in Study 1. There were no significant effects, including that for trial type, $F(1, 14) = 0.23$, $p = .64$, partial $\eta^2 = .016$ (Figure 3). Only 6 of the 16 infants' searches were longer on the PN-PN trial than on the CN-PN trial, nonsignificant by a sign test.

Why did 16-month-olds not search significantly longer on the PN-PN trial than on the CN-PN trial? One possibility is that 16-month-olds simply fail at this type of search task. This alternative can be ruled out by prior demonstrations that infants as young as 10 – 12 months succeed in similar search tasks when given spatiotemporal or property/kind information (e.g., Feigenson & Carey, 2003; Van de Walle et al., 2000; Xu & Baker, 2005). Another possibility is that 16-month-olds are unable to use verbal information in search tasks. This alternative can be ruled out by the findings of Xu et al. (2005), revealing that infants as young as 12 months can use verbal information successfully in a similar search task. Given these considerations, we interpret the failure in Study 3 as reflecting the fact that, unlike 20-month-olds, 16-month-olds did not distinguish semantically

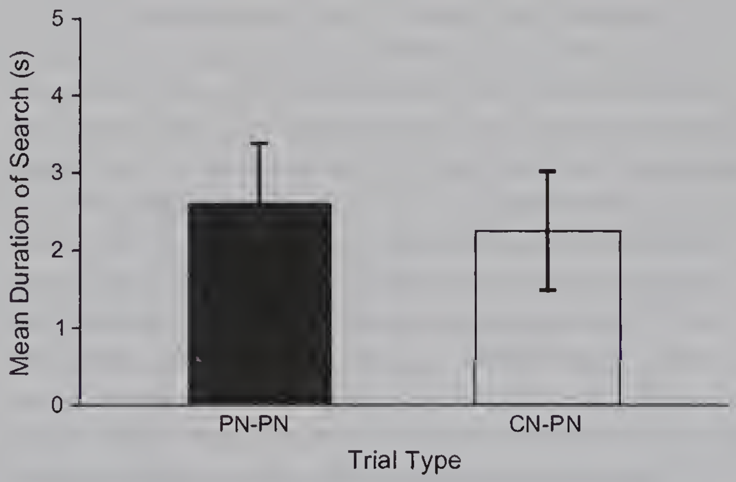

Figure 3. Results of Study 3.
Note. Bars represent 1 *SE*. PN = proper name; CN = count noun.

between proper names and count nouns and as a result were no more likely to expect two objects after hearing two proper names than after hearing the combination of a count noun followed by a proper name.

The results of Study 3 (with 16-month-olds) differed clearly from those of Study 1 (with 20-month-olds). In Study 3, the effect of trial type was not significant, the effect size was small (partial $\eta^2 = .016$), and a nonsignificant number of infants (6/16) showed the effect. In Study 1, recall that the effect of trial type was significant, the effect size was larger (partial $\eta^2 = .434$), and a significant number of infants (12/16) showed the effect. To follow up these separate analyses, we performed a direct between-study comparison. We combined the search duration data from Studies 1 and 3 and conducted a 2 × 2 × 2 mixed ANOVA, with age (16-month-olds in Study 3; 20-month-olds in Study 1) and trial order (PN-PN first, CN-PN first) as between-subjects factors and trial type (PN-PN, CN-PN) as a within-subjects factor. In this follow-up analysis, there was a main effect of trial type, $F(1, 28) = 6.23$, $p = .019$, partial $\eta^2 = .182$, but the expected interaction between trial type and age failed to reach significance, $F(1, 28) = 3.16$, $p = .086$, partial $\eta^2 = .101$. The fact that this interaction approached but did not attain significance is consistent with the possibility that sensitivity to the semantic distinction between proper names and count nouns is starting to emerge at 16 months.

These findings converge with previous results from Bélanger and Hall (2006), who found that 16-month-olds, unlike 20-month-olds, failed to distinguish between proper names and count nouns in a categorization task involving word extension. Note that Bélanger and Hall's task implicated very different abilities from those implicated by the current task: Their task assessed whether infants can extend novel proper names and count nouns appropriately; the current task, in contrast, assessed whether infants can use the proper name–count noun distinction to determine the number of objects present in a situation in which numerical identity is ambiguous. The agreement between the results from the two tasks thus lends further support to the proposal that infants acquire knowledge of the distinct semantics of these lexical categories between 16 and 20 months.

Study 4 was an attempt to clarify the basis for the trial type effect uncovered in Study 1. In Study 1, the second novel word was presented in the same sentence frames on both trials (i.e., as a proper name). However, the first novel word was presented in different sentence frames on the two trials, depending on whether it was a proper name or a count noun. We have suggested that infants relied on the difference between the sentence frames carrying the first word on the two trials to guide them in our task. However, we were also aware of a prosodic difference between trials associated with the sentence frames containing the *second* novel word. On the PN-PN trials (where the previous word had also been a proper name), the experimenter tended to place stress on the word "his" in the initial sentence frame, "His name is ___"; however, on the CN-PN trials (where the previous word had been a count noun), she tended to place\ emphasis on the word "name" in the same sentence frame. We wondered whether infants relied on this prosodic difference to guide their interpretations.

We began to address this issue by seeking evidence that adults could detect a prosodic difference between the initial sentence frames containing the second word when presented on the two trials. We obtained the audio clips of the presentation of this sentence frame from both trials from all 16 children in Study 1. This yielded 32 clips, each involving the presentation of a novel proper name. For 16 of the recordings, the word had been preceded by another proper name (i.e., on the PN-PN trial); for the other 16, the preceding word had been a count noun (i.e., on the CN-PN trial). Four adults listened to all these clips in a random order and decided, for each one, whether they heard stress on the word "his" or on the word "name."

We scored each adult's set of responses out of 32 to reflect their accuracy in grouping the recordings into those from the PN-PN trial and those from the CN-PN trial. A score of 50% (16/32) was taken to be random performance, and scores higher than 50% were taken to reflect successful categorization (i.e., judging stress on "his" on a PN-PN trial). All four adults were perfect (32/32) in their grouping. They thus detected a prosodic difference between the initial sentence frames containing the second word on the two trials in Study 1.

Our next step was to determine whether the prosodic difference in Study 1 contributed to the trial type effect discovered in that study. To do so, we conducted Study 4 as a replication of Study 1 with one change: We presented the second word with a similar prosody on the two trials.

Study 4

Method

Participants. Participants were 16 infants (8 girls and 8 boys), with an average age of 20.7 months (range = 18.0–22.4 months). None had taken part in any previous study. We also tested, but excluded from the final sample, 7 infants for failing to complete the task and 2 for having a search time longer than 2.5 *SDs* from the mean on at least one trial.

Materials. These were the same as in Study 1.

Design and procedure. These were the same as in Study 1 except that the experimenter was trained to present the second word on the two trials using similar prosody.

Data analysis. Coding was carried out as in Study 1. Intercoder agreement was calculated to be $r = 1.0$.

Before analyzing the data, we conducted a manipulation check. We enlisted the same four adults who coded the prosody of the initial sentence frames containing the second word for the Study 1 data to partition clips of these sentence frames for the Study 4 data, given the same directions. Recall that for the Study 1 data, all four adults had perfectly divided the clips into those from the PN-PN trial and those from the CN-PN trial (i.e., the average score was 100%). In contrast, adults in Study 4 were essentially random in the accuracy of their grouping. The average accuracy score was 51% (15/32, 16/32, 17/32, and 17/32). This result suggests that adults did not detect a systematic prosodic difference in the way the initial sentence frames containing the second word were presented on the two trials. This finding does not imply that we eliminated all prosodic differences or that infants similarly found no systematic prosodic difference between the sentences containing the second words on the two trials. However, the finding does suggest that the prosodic difference between trials identified in Study 1 was significantly reduced in Study 4.

Results and Discussion

As in Study 1, 20-month-olds searched longer on the PN-PN trial than on the CN-PN trial. We conducted the same ANOVA as in Study 1. The only significant effect was that for trial type, $F(1, 14) = 7.24$, $p = .018$, partial $\eta^2 = .341$ (Figure 4). As in Study 1, 12 of the 16 infants' second reaches were longer on the PN-PN trial than on the CN-PN trial, $p = .038$ (one tailed) by a sign test.

Despite the fact that we controlled the prosodic information provided with the second word on the two trials, 20-month-olds still appeared to distinguish between proper names and count nouns, and they again seemed more likely to expect two objects in the box when given two proper names than when given the combination of a count noun followed by a proper name. This result suggests that the prosodic difference identified by adults in the data from Study 1 was not the source of the trial type effect observed in that study; instead, the finding suggests that the source of the effect was the difference between the sentence frames in which the proper names and count nouns appeared.

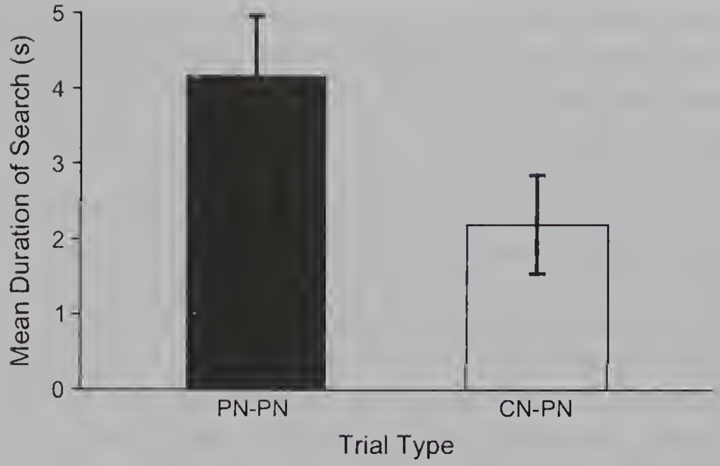

Figure 4. Results of Study 4.
Note. Bars represent 1 *SE*. PN = proper name; CN = count noun.

Study 5 was an attempt to clarify further the effect of trial type observed among 20-month-olds. As noted in Study 1, one interpretation is that the effect stems from infants' understanding of the distinct semantics of proper names and count nouns, coupled with adherence to the contrast principle. An alternative, however, is that the effect reflects infants' understanding of the pragmatic implications of a speaker's using two novel object labels from the same lexical category rather than two labels from different lexical categories. On this alternative, infants infer that a speaker who uses two novel labels from the same lexical category likely intends to use them contrastively to refer to two different objects, whereas they draw no such inference about a speaker who uses two words from different lexical categories. On this alternative, the trial type effect is not due to specific knowledge about the distinct semantics of proper names and count nouns.

In Study 5, we tested between these alternatives by replicating Study 4 but replacing proper name sentence frames with adjective sentence frames. Unlike proper names, which refer to individual objects, adjectives refer to object properties. Recent research suggests that infants have some understanding of the link between adjectives and object properties by as young as 14 months (e.g., Booth & Waxman, 2003; Waxman, 1999). If the findings we obtained with 20-month-olds in our previous studies reflect infants' inferences about a speaker's intended use of two words from the same lexical category rather than two words from different lexical categories, then we should have replicated the significant trial type effect observed in Study 4. In other words, we should have found that the trial type effect that emerged when we compared two proper names to the combination of one count noun followed by one proper name also emerged equivalently when we compared two adjectives to the combination of one count noun followed by one adjective.

If, however, the effect observed with 20-month-olds in our previous studies reflects infants' knowledge of the distinct semantics of proper names and count nouns, coupled with adherence to the contrast principle, then the trial type effect should have been *weaker* in Study 5. To understand this expectation, note that the contrast principle makes different predictions about the interpretation of adjectives in our task than it does about the interpretation of proper names. Allowing two proper names for one object would violate the contrast principle because the words would have the same meaning (i.e., they would both be labels for the same individual object). Allowing the combination of one count noun followed by one proper name would *not* violate contrast, however, because the words would have different meanings (i.e., one would label an object category and the other would label an individual object). As a result, infants in our task should reject two proper names for one object but be willing to accept the combination of one count noun followed by one proper name. This prediction was supported by the significant trial type effect observed with 20-month-olds in the previous studies.

If adjectives replace proper names in our task, however, the prediction changes. Allowing two novel adjectives for one object would *not* necessarily violate the contrast principle because the words could have different meanings (i.e., they could be labels for different object properties). Similarly, allowing one count noun followed by one adjective would not violate the contrast principle because the two words would have different meanings (i.e., one would label an object category and the other would label an object property). As a result, infants should be willing to accept both the possibility that two adjectives apply to the same object as well as the possibility that the combination of one count noun followed by one adjective applies to that object (see also Diesendruck, Hall, & Graham, 2006; Hall & Graham, 1999). The trial type effect that we observed with 20-month-olds in our previous studies should thus be weaker when we replace proper names with adjectives in our task.

Study 5

Method

Participants. Participants were 16 infants (8 girls and 8 boys), with an average age of 20.6 months (range = 18.1 – 22.5 months). None had taken part in any previous study. We also tested, but excluded from the final sample, 4 infants for failing to complete the task and 2 for having a search time longer than 2.5 *SDs* from the mean on at least one trial.

Materials. These were the same as in Study 4.

Design and procedure. These were similar to those used in Study 4, except that the novel words modeled as proper names in Study 4 were now modeled as adjectives. As a result, the two trials were named the adjective – adjective (ADJ-ADJ) trial and the count noun – adjective (CN-ADJ) trial. The five sentence frames we used to present the adjectives were similar to those used to present proper names in Study 4: "Look! He is really FEP! Do you see? He is very FEP! Look! He is very FEP! I think he wants to come see you! Do you want to play with him? He is very FEP! Look, he is very FEP! I'm going to put him back inside the box!"

Data analysis. Coding was carried out as in Study 1. Intercoder agreement was calculated to be $r = .99$.

As in Study 4, we conducted a manipulation check to determine whether adults detected any systematic prosodic difference between the sentence frames containing the first mention of the second word on the two trials (i.e., "He is really ___"). As in Study 4, the four adult raters were essentially random in the accuracy of their partitioning of the 32 recordings into those that were from the ADJ-ADJ trial (i.e., judged stress on "he") and those that were from the CN-ADJ trial (i.e., judged no stress on "he"). The average accuracy score was 50% (18/32, 18/32, 13/32, and 15/32). This finding suggests that adults did not detect any systematic prosodic difference between the initial sentence frames containing the second novel word on the two trials.

Results and Discussion

Twenty-month-olds did not search significantly longer on the ADJ-ADJ trial than on the CN-ADJ trial. We conducted the same ANOVA as in Study 1. There were no significant effects, including that for trial type, $F(1, 14) = 1.38$, $p = .26$, partial $\eta^2 = .089$ (Figure 5). Only 8 of the 16 infants' searches were longer on the ADJ-ADJ trial than on the CN-ADJ trial, nonsignificant by a sign test.

When we replaced proper names with adjectives in the task from Study 4, 20-month-olds did not search significantly more persistently after hearing two novel words from the same lexical category (two adjectives) than after hearing two words from different lexical categories (one count noun followed by one adjective). This discovery suggests that the significant

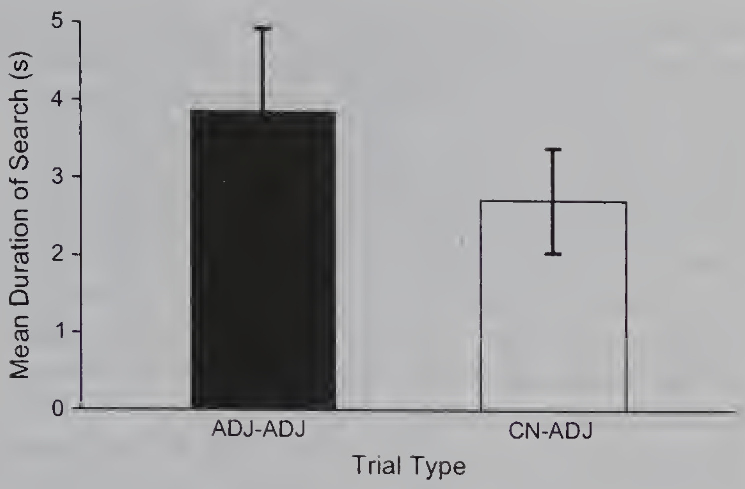

Figure 5. Results of Study 5.
Note. Bars represent 1 *SE*. ADJ = adjective; CN = count noun.

trial type effect observed with 20-month-olds in Study 4 was not driven solely by our use of two words from the same lexical category rather than two words from different lexical categories. Instead, the result offers support for the claim that the effect reflected infants' knowledge of the distinct semantics of count nouns and proper names, coupled with adherence to the principle of contrast.

The results of Study 5 (with adjectives) clearly differed from those of Study 4 (with proper names). In Study 5, the trial type effect was not significant, the effect size was modest (partial η^2 = .089), and a nonsignificant number of infants (8/16) showed the effect. In Study 4, however, the effect of trial type was significant, the effect size was larger (partial η^2 = .341), and a significant number of infants (12/16) showed the effect. To follow up these separate analyses, we carried out a direct between-study comparison. We combined the search duration data from Studies 4 and 5 and conducted a 2 × 2 × 2 mixed ANOVA, with lexical category (adjectives in Study 5, proper names in Study 4) and trial order (two words from same lexical category first, two words from same lexical category second) as between-subjects factors, and trial type (two words from same lexical category, two words from different lexical categories) as a within-subjects factor. In this follow-up analysis, there was a significant effect of trial type, $F(1, 28) = 6.52$, $p = .016$, partial η^2 = .189, but the expected interaction between lexical category and trial type was not significant, $F(1, 28) = 0.46$, $p = .50$, partial η^2 = .016.

Close inspection of the results from Studies 4 and 5 reveals a way to reconcile the apparent conflict between the nonsignificant trial type effect in the analysis of Study 5 and the nonsignificant interaction between lexical category and trial type in the cross-study analysis. In Study 5, although the trial type effect was nonsignificant, the difference between trial means was in the predicted direction, indicating that infants had a weak tendency to expect two objects upon hearing two adjectives. However, the trial type effect was more than three times *larger* when the study involved proper names (partial η^2 = .341) than when it involved adjectives (partial η^2 = .089). The stronger effect in Study 4 (with proper names) and the weaker effect in Study 5 (with adjectives) thus lend support to two claims. First, infants *did* distinguish between the use of proper names and adjectives in our task. This discovery suggests that the effect uncovered in Study 4 reflects infants' knowledge of the semantic distinction between proper names and count nouns, along with adherence to the principle of contrast. Second, infants also had a weaker pragmatic tendency to infer that a speaker who used two words from the same lexical category (either two proper names or two adjectives) intended the words to apply to two different objects.

General Discussion

The results of these five studies provide the first evidence in the literature that infants' emerging understanding of distinct lexical-category-to-meaning links guides them in the fundamental task of object individuation. The findings make three main contributions. First, they reveal a previously unidentified source of information available to drive individuation in infancy. Prior work has established that by 12 months (or earlier), infants can use information about both spatiotemporal differences and property–kind differences between objects to guide individuation (Bonatti, Frot, Zangl, & Mehler, 2002; Wilcox & Baillargeon, 1998; Wilcox & Schweinle, 2002; Xu & Baker, 2005; Xu & Carey, 1996; Xu, Carey, & Quint, 2004). Previous research has also identified a role for language. For example, 10-month-old infants often fail to use property–kind differences between objects to individuate them in a complex task, but they may succeed when the objects receive distinct count noun labels (Xu, 2002). Moreover, Xu et al. (2005) found that 12-month-olds who heard two different novel count nouns were more likely to infer the presence of two objects hidden inside an opaque box than those who heard one count noun repeated. The current work reveals that, in addition to these cues, 20-month-old infants can use lexical category information to guide object individuation. Specifically, they can exploit this information to disambiguate an event that involves two sequential appearances of an object.

It would be interesting to push this line of research further by removing the presence of the object(s) from the task. The results from the current task do not allow us to determine whether infants needed to see the object appearances in order to use the lexical category information appropriately in drawing inferences about the number of objects hidden in the box. Eliminating the objects from the task would enable a test of whether infants can use lexical category information *alone* to set up a mental model of the number of objects present in an ambiguous scene. Moreover, if we take the presentation of one or more objects to be a defining property of an object individuation task, infants' success on this modified task would suggest that they have the ability to use lexical category cues to predict the number of objects present in the ambiguous situation, without individuating objects per se. In future work, it would be interesting to examine infants' use of lexical category information in this type of modified task (see Dewar & Xu, 2007; Xu et al., 2005).

Second, the results provide the first evidence from a manual search task that by 20 months, infants have acquired knowledge of appropriate semantic distinctions among three word categories (proper names, count nouns, and adjectives). The results are consistent with a body of research reporting knowledge of several distinct lexical-category-to-meaning links in children younger than 2 years (e.g., Booth & Waxman, 2003; Echols & Marti, 2004; Waxman, 1999; Waxman & Booth, 2001; Waxman & Markow, 1998). More specifically, the current results corroborate recent findings from a study that used a categorization task involving word extension to investigate infants' knowledge of the distinct semantics of proper names and count nouns (Bélanger & Hall, 2006). In that study, as in the current one, 20-month-olds but not 16-month-olds distinguished appropriately between these two lexical categories. The agreement between the results of the two studies provides evidence that lexical category knowledge is available to guide infants in a manual search task as soon as it can be used to direct them in word extension. The convergence between the search and the word extension results also bolsters the claim that knowledge of lexical-category-to-meaning links for proper names and count nouns first arises between 16 and 20 months.

Finally, the findings offer new evidence that infants use the principle of contrast in the acquisition of novel words. The effects we observed among 20-month-olds cannot be due solely to their knowledge of the semantics of different lexical categories. Infants must also have an understanding of circumstances under which the use of two novel words implies reference to two different objects, such as when the two words would violate the contrast principle (Clark, 1993) if they referred to just one object. In our task, two novel proper names for one object would violate the contrast principle because both words would have the same meaning (i.e., the words would both refer to the *same* individual object). Two novel adjectives for one object, however, would not necessarily violate the contrast principle because they could be taken to have different meanings (i.e., the words could refer to *different* object properties). The combination of a count noun followed by a proper name or a count noun followed by an adjective for one object would not violate contrast because the two terms would have different meanings (i.e., one would refer to an object category and the other to an individual object or an object property). It is possible that infants represent the contrast principle as a semantic constraint on the possible meanings that can be assigned to novel words, but it is also possible that it is a pragmatic assumption about a speaker's intended use of words within a discourse context. One piece of evidence favoring the pragmatic account is that many objects do have more than one proper name (e.g., one man may be called "William," "Bill," or "Mr. Smith" by different people and/or in different settings); however, it is unclear whether 20-month-olds possess this knowledge (for further discussion of pragmatics and the contrast principle, see Bloom, 2000; Clark, 1993; Diesendruck, 2005; Diesendruck & Markson, 2001).

The results from Study 5 also suggest that infants have an additional, weaker expectation that a speaker who uses two novel words from a single lexical category intends to refer to two different objects, even when the words would not necessarily violate the contrast principle if applied to one object (as in the case of two novel adjectives). Further research manipulating the conditions under which infants are exposed to multiple novel words for objects should help clarify the nature of their assumptions about the possible semantic relations that can hold among them.

Development of Emotional and Behavioral Regulation in Children Born Extremely Preterm and Very Preterm: Biological and Social Influences

Caron A. C. Clark
University of Canterbury

Lianne J. Woodward
University of Canterbury and Van der Veer Institute for Parkinson's and Brain Research

L. John Horwood and Stephanie Moor
University of Otago

This study describes the development of emotional and behavioral regulation in a regional cohort of children born extremely preterm (<28 weeks gestational age, n = 39), very preterm (<34 weeks gestational age, n = 56), and full term (n = 103). At 2 and 4 years, children born at younger gestational ages demonstrated poorer self-regulation across multiple contexts spanning observed interactions, formal cognitive testing, and parental report of child behavior at home. Among children born preterm, the 2 strongest predictors of impairments in self-regulation were the presence of moderate-to-severe cerebral white matter abnormalities on neonatal magnetic resonance and a less sensitive parenting style when children were aged 2 years. Findings support the importance of early neurological development and parenting for developing regulation in children born very preterm.

As more sophisticated medical intensive care has rescued ever smaller babies, increasing concerns about the longer term social and emotional consequences for these children have been raised. Findings suggest that, by middle childhood, children born very preterm are almost three times more likely to meet *Diagnostic and Statistical Manual of Mental Disorders (DSM)* criteria for attention-deficit hyperactivity disorder and are at elevated risk for depression, anxiety disorders, and behavioral problems compared to their full-term peers (Bhutta, Cleves, Casey, Cradock, & Anand, 2002; Botting, Powls, Cooke, & Marlow, 1997; Breslau et al., 1996; Farooqi, Hagglof, Sedin, Gothefors, & Serenius, 2007; Horwood, Mogridge, & Darlow, 1998). Relatedly, very preterm children have also been found to have higher rates of social withdrawal and peer victimization (Breslau et al., 1996; Gardner et al., 2004; Nadeau, Boivin, Tessier, Lefebvre, & Robaey, 2001; Nadeau, Tessier, Boivin, Lefebvre, & Robaey, 2003).

Despite initial optimism that these emotional and behavioral difficulties would improve with age, growing evidence now suggests that these problems often persist into adolescence and, to some extent, early adulthood (Cooke, 2004; Gardner et al., 2004; Hack et al., 2002; Indredavik, Vik, Heyerdahl, Kulseng, & Brubakk, 2005). For example, 15- to 16-year-old teenagers born extremely preterm (≤ 28 weeks gestation) have been found to report 2 to 3 times more emotional problems and to have lower rates of normative peer risk taking and social engagement than teenagers born full term (Gardner et al., 2004). Parents and teachers also rated these teens as showing higher rates of emotional problems, hyperactivity, and peer relationship problems, with these difficulties impacting on home life, learning, friendships, and leisure. These findings highlight the presence of persistent mental health and social impairments among children and adolescents born very preterm. Furthermore, there is evidence to suggest that risks of later problems are greatest among those born at the lower limits of viability, that is, extremely preterm (< 28 weeks) or extremely low birth weight (< 1,000 g; Hack et al., 1994; Klebanov, Brooks-Gunn, & McCormick, 1994).

This research was funded by grants from the Neurological Foundation of New Zealand, Lottery Grants Board, Canterbury Medical Research Foundation, and the Health Research Council of New Zealand. Special thanks to Associate Professor Terrie Inder (pediatric neurologist) and Dr. Scott Wells (radiologist) for MR imaging analysis, others in the research team (Dr. Patricia Champion, Dr. Nicola Austin, Jacqueline Knight, Kelly Hood, Michelle VanDyk, Michelle Davey. and Carole Spencer), and most importantly to the study families for their willingness to share their children's lives with us.

Although clear linkages have been demonstrated between preterm birth and children's later psychosocial risks during childhood and adolescence, much less is known about the early developmental precursors of these later difficulties, the manner in which such difficulties may develop and manifest over early childhood, or the clinical and socioenvironmental factors that place very preterm children at later risk. Such information is essential for the identification of at-risk infants and the development of effective early intervention strategies to assist these children and their families. Accordingly, the goal of this study was to address these important research gaps using prospective longitudinal data from a regional cohort of very preterm infants (a) to examine the early development of emotional and behavioral regulation of very preterm children and (b) to examine, within the preterm group, clinical and socioenvironmental predictors of early regulatory delay and/or impairment. A review of existing evidence relating to the importance of self-regulation for psychosocial development, as well as a consideration of the factors that may place children born preterm at elevated risk of regulatory problems, is provided below.

Self-Regulation and Homeostasis in the Preterm Infant

Self-regulation refers to the ability to modulate emotion, self-soothe, delay gratification, and tolerate change in the environment (DeGangi, 2000; Kopp, 1982). Temperament theorists also emphasize key biological processes such as attention, approach, avoidance, and inhibition in the modulation of arousal and reactivity (Goldsmith et al., 1987). The toddler and early preschool years represent an important period for the emergence of self-regulation (Kopp, 1982). Internal homeostasis allows children to maintain optimal arousal, attend to the external environment, explore, and learn. Over this period, drawing on internal working models gained from dyadic attachment relationships and biological maturational processes, children gradually become more efficient at postponing gratification, soothing and calming themselves to prevent emotional lability, and sustaining and flexibly manipulating their attention. Such abilities are integral to the development of advanced social, emotional, and cognitive function (Eisenberg et al., 2000; Lengua, 2003).

Given the importance of self-regulation for children's emerging emotional, behavioral, and social development, it has increasingly been recognized as a potentially important marker of later psychosocial risk (Cole, Michel, & Teti, 1994; Lawson & Ruff, 2004). Certainly, good theoretical support exists for the role of early emotional dysregulation in anxious-depressive disorders (Calkins, 1994; Dahl, 2003). Also, although learning difficulties and attentional disorders are commonly only diagnosed following school entry, children who develop such difficulties have been found to show signs of poor attentional regulation as preschoolers (Lawson & Ruff, 2004). Given these findings, self-regulation is now increasingly recognized as an important developmental task of early childhood.

There are several reasons to suspect that children born very preterm may be vulnerable to regulatory difficulties in early childhood. In particular, clinical and observational studies suggest that very young preterm infants are more excitable and irritable, have more difficulty regulating their arousal and motor responses, and have more difficulty directing their attention to salient stimuli (Brown, Doyle, Bear, & Inder, 2006; Eckerman, Oehler, Medvin, & Hannan, 1994; Hughes, Shults, McGrath, & Medoff-Cooper, 2002; Mouradian, Als, & Coster, 2000). Preterm infants characterized by higher levels of medical risk have also been found to have more negative facial expressions, disorganized movement, and poorer attentional control when overstimulated compared to their lower risk, preterm peers (Eckerman et al., 1994). In another study, parents of very preterm infants reported that their infants had less regular sleeping, feeding, and elimination patterns; were less intense in their responses; and were more withdrawing from new situations, stimuli, or places than full-term infants (Hughes et al., 2002). Although some improvement was evident on measures of activity and regularity by age 6 months, preterm infants remained less adaptable. Consistent with these parent report studies, several observational studies have shown that trained independent observers tend to rate very preterm infants as showing fewer positive and more negative expressions and as exhibiting more difficulties transitioning across tasks, compared to term-born infants (Landry, Garner, & Swank, 1996; Segal et al., 1995). Furthermore, preterm infants who have sustained brain insult such as intraventricular hemorrhage have also been found to display less sociability and less behavioral approach, suggestive of dampened behavioral reactivity (Garcia Coll et al., 1988).

Taken together, despite differences in methodological approaches (neurobehavioral examination, temperament scales, and direct observation), there is now converging evidence that, during the 1st year of life, infants born very preterm experience difficulties in the regulation of arousal and emotional responses and in flexibly allocating and sustaining their attention. Furthermore, as has been shown with later cognitive and behavioral outcomes, there is evidence of a dose–response relationship, with risks of later difficulties increasing with decreasing gestational age (Duffy, Als, & McAnulty, 1990; Mouradian et al., 2000). However, the extent to which these regulatory difficulties persist or change over the toddler and preschool years has yet to be established.

Clinical and Sociofamilial Factors Associated With Later Regulatory Abilities in Children Born Very Preterm

A second issue raised by these childhood findings concerns the clinical and socioenvironmental risk factors that place very preterm children at elevated risk of early and persistent regulatory difficulties. To date, few studies have examined the role of perinatal factors such as the degree of immaturity, infant illness severity, or the extent of early cerebral neuroanatomical abnormalities in accounting for individual differences in regulation and behavioral adjustment. It is possible that the artificial environment of the neonatal intensive care unit, accompanied by the pain and stress of these medical procedures, may have ongoing consequences for children's homeostatic regulation of arousal (Graham, Heim, Goodman, Miller, & Nemeroff, 1999; Porges, 1996). For example, infants who are exposed to more painful medical procedures have been found to have higher levels of cortisol at follow-up points during the first 2 years of life, suggesting that these early medical experiences may permanently alter the set point of arousal in these infants (Grunau, Weinberg, & Whitfield, 2004).

Accompanying these medical experiences, neonatal magnetic resonance (MR) imaging studies indicate that the majority of infants born preterm have white matter abnormalities, including signal abnormalities, loss of volume, cystic abnormalities, enlarged ventricles, thinning of the corpus callosum, and decreased myelination (Inder, Warfield, Wang, Huppi, & Volpe, 2005). Although some studies have demonstrated a relationship between neurological abnormalities and neurobehavior in these infants at term age (Brown et al., 2006; Mouradian et al., 2000), no studies to date have examined the relationship between MR findings and emotional and behavioral outcomes in preschool-aged children born very preterm.

Even less consideration has been given to the contribution of social contextual factors such as the availability of socioeconomic resources, maternal psychological well-being, and parenting, despite clear evidence demonstrating the importance of these factors for children's behavioral development (Colman, Hardy, Albert, Raffaelli, & Crocket, 2006; Shaw, Keenan, Vondra, Delliquadri, & Giovannelli, 1997; Supplee, Shaw, Hailstones, & Hartman, 2004). This is important, given some suggestion that children born very preterm who are at high medical risk may benefit from parenting that is sensitive and nonintrusive in timing and nature (Forcada-Guex, Pierrehumbert, Borghini, Moessinger, & Muller-Nix, 2006; Landry et al., 1996). Other contextual factors that may be influential include lower socioeconomic resources, lower maternal education, and maternal depression (Murray & Cooper, 1997; O'Connor, Heron, Glover, & Alspac Study, 2002; Silk, Shaw, Skuban, Oland, & Kovacs, 2006). Such risk factors have been shown to be more common among parents of preterm infants (Kersting et al., 2004; Miles, Holditch-Davis, Schwartz, & Scher, 2007). Examination of both clinical and sociofamilial factors will be important in developing a better understanding of the processes shaping the developmental pathways toward regulatory competence in children born preterm.

Two obstacles to a better understanding of the development of self-regulation in this high-risk population are the paucity of reliable and valid measures of self-regulation in preschool children and the tendency for many studies to rely solely on parent report measures of infant temperament and behavior (e.g., Delobel-Ayoub et al., 2006; McCormick, Workman-Daniels, & Brooks-Gunn, 1996). Porges (1996) has recommended that the measurement of self-regulatory capacities be based on behaviors such as the quality, quantity, and appropriateness of body movements and coordination of emotional responses. Thus, behavioral observation in a demanding task environment may provide a valuable complement to parent report measures of self-regulation. In addition, others have stressed the importance of context and the goal at hand in assessing a child's regulatory competence (Cole et al., 1994; Thompson, 1994). For example, although particular strategies for the regulation of emotion may be appropriate at one age or in one context, they may become less adaptive or acceptable as children age or as they enter more challenging social situations. Thus, effective self-regulation is multidimensional, influenced by contextual demands, and reliant on a range of processes. These processes span arousal and attentional flexibility, the expression of affect, and the ability to transition fluently across situations.

Drawing on these conceptual and measurement recommendations, we adopted a multimethod measurement approach in order to examine the development of preschool children's emotional and behavioral regulation at ages 2 and 4 years in a cohort of children born preterm and full term. Given previous evidence showing that children born extremely preterm may be especially vulnerable to later developmental challenges, the effect of gestational age on later regulatory outcomes was also considered. We hypothesized that, relative to their full-term peers, children born preterm would show impaired emotional and behavioral regulation across all assessment contexts, with those born extremely preterm being most impaired. The specific aims of the study were as follows.

1. To describe the emotional and behavioral regulation of children born extremely preterm, very preterm, and full term at ages 2 and 4 years (corrected for gestational age at birth). Repeated measures of regulation across the two time points included observed child behavior during structured parent – child interaction and during cognitive testing, in addition to parent report.
2. To describe the development of self-regulation over the period from 2 to 4 years in children born very (< 33 and > 28 weeks) and extremely (≤ 28 weeks) preterm.
3. To examine, within the preterm sample, the extent to which impairment in the development of self-regulation between the ages of 2 and 4 years could be explained by a range of risk factors spanning infant clinical and sociofamilial factors. These included intrauterine growth restriction (IUGR, defined as a birth weight below the 10th percentile for gestational age), chronic lung disease (defined as oxygen use at 36 weeks), patent ductus arteriosis (PDA, a circulatory condition arising as a consequence of an immature heart), administration of antenatal steroids, necrotizing enterocolitis (NEC, a condition of the intestine), white matter abnormalities as measured by MR, maternal education, family socioeconomic status (SES), maternal mental health, experience of early intervention, and parenting style.

Method

Participants

The study included three groups of children who were recruited as part of a prospective longitudinal study aimed at examining the developmental and neuropsychological outcomes associated with prematurity. These study groups are described below.

Children Born Very Preterm and Extremely Preterm

The first two groups were drawn from a regional cohort of 102 children born very preterm (≤ 33 weeks) and/or very low birth weight (< 1,500 g) who were admitted consecutively to a Level III neonatal intensive care unit at Christchurch Women's Hospital, New Zealand from November 1998 to February 2001. Families were invited to participate in the study by a research nurse based at the hospital. Exclusion criteria included infant congenital abnormalities and non-English-speaking parents. Ninety-two percent of all eligible infants were recruited. These infants had a mean birth weight of 1,069 g (range = 385 – 1,790 g) and a mean gestational age of 28 weeks (range = 23 – 33 weeks). All children born preterm were assessed throughout the perinatal period, at term equivalent, and at 2 and 4 years (corrected for gestational age at birth). Excluding deaths (n = 3), sample retention to age 2 years was 97%, with 2 children untraced and 1 overseas relocation. An additional child was unable to be assessed due to severe visual impairment. At age 4 years, sample retention was 99%. Although one family refused to participate at this follow-up point, the 3 children who were not seen at age 2 years were successfully retraced at age 4 years. Because prior research has suggested that gestational age is a robust predictor of developmental outcome, all children born preterm were divided into two groups: (a) those born between 28 and 33 weeks gestation (n = 59) and (b) those born prior to 28 weeks gestation (n = 39). Sample stratification was based on gestational age rather than birth weight to avoid the confounding effects of IUGR. These gestational cut points are widely used to define the extent of immaturity at birth and have good predictive validity (Anderson, Doyle, & the Victorian Infant Collaborative Study, 2003; Doyle, Casalaz, & the Victorian Infant Collaborative Study Group, 2001; Foster-Cohen, Champion, Edgin, & Woodward, 2007; Horwood et al., 1998; Marlow, 2004; Nadeau et al., 2001). In the interests of consistency, these groups of children are collectively referred to as children born preterm.

Children Born Full Term

In addition to the preterm groups, a group of 103 children born full term (> 37 weeks gestation at birth) was recruited at age 2 years. These children were identified from the hospital birth record database by selecting, in an alternative manner, a child of the same gender born two deliveries prior to, or following, the birth of each preterm child. These children had a mean gestational age of 40 weeks (range = 38 – 41 weeks) and a mean birth weight of 3,592 g (range = 2,700–4,630 g). Consistent with the preterm groups, children with congenital abnormalities and those from non-English-speaking families were excluded. Of the families identified, 62% participated in the study. Of those not recruited, 47% were untraced, 12.5% had relocated overseas, 12.5% refused, and 28% initially agreed to participate but were unable to attend their 2-year assessment within the specified time frame (±2 weeks) due to illness or family circumstances. No significant between-group differences were found between nonrecruited and recruited term-born children on measures of gestational age, birth weight, family SES, or the proportion of Maori families. (The Maori population are the indigenous people of New Zealand. Although they make up about 12% of the general population, only 10% of all Maori live in the South Island; Statistics New Zealand, 2001.) At age 4 years, 96% of this sample was reassessed, with 2 children unable to be traced and 2 families declining to participate.

For children participating in the 2- and 4-year follow-up assessments, no significant differences were found across the three groups on measures of child gender ($p = .92$), ethnic distribution ($p = .64$), or maternal age at birth ($p = .89$). However, children born very preterm or extremely preterm were more likely to come from families of lower SES ($p < .001$), and their mothers were more likely to have left school before the age of 16 years ($p < .01$).

Measures

Figure 1 describes the data collection points and the key measures obtained for this study. As illustrated, a series of common measures assessing aspects of children's emotional, behavioral, and attentional regulation were administered at the ages of 2 and 4 years. These measures were selected based on existing research and theory and included (a) observational ratings of children's behavior during a structured parent–child interaction task, (b) independent tester ratings of child behavior during cognitive assessments, and (c) an adaptation of the parent-reported Emotion Regulation Checklist (Shields & Cicchetti, 1997). A detailed description of each of these study measures is given below.

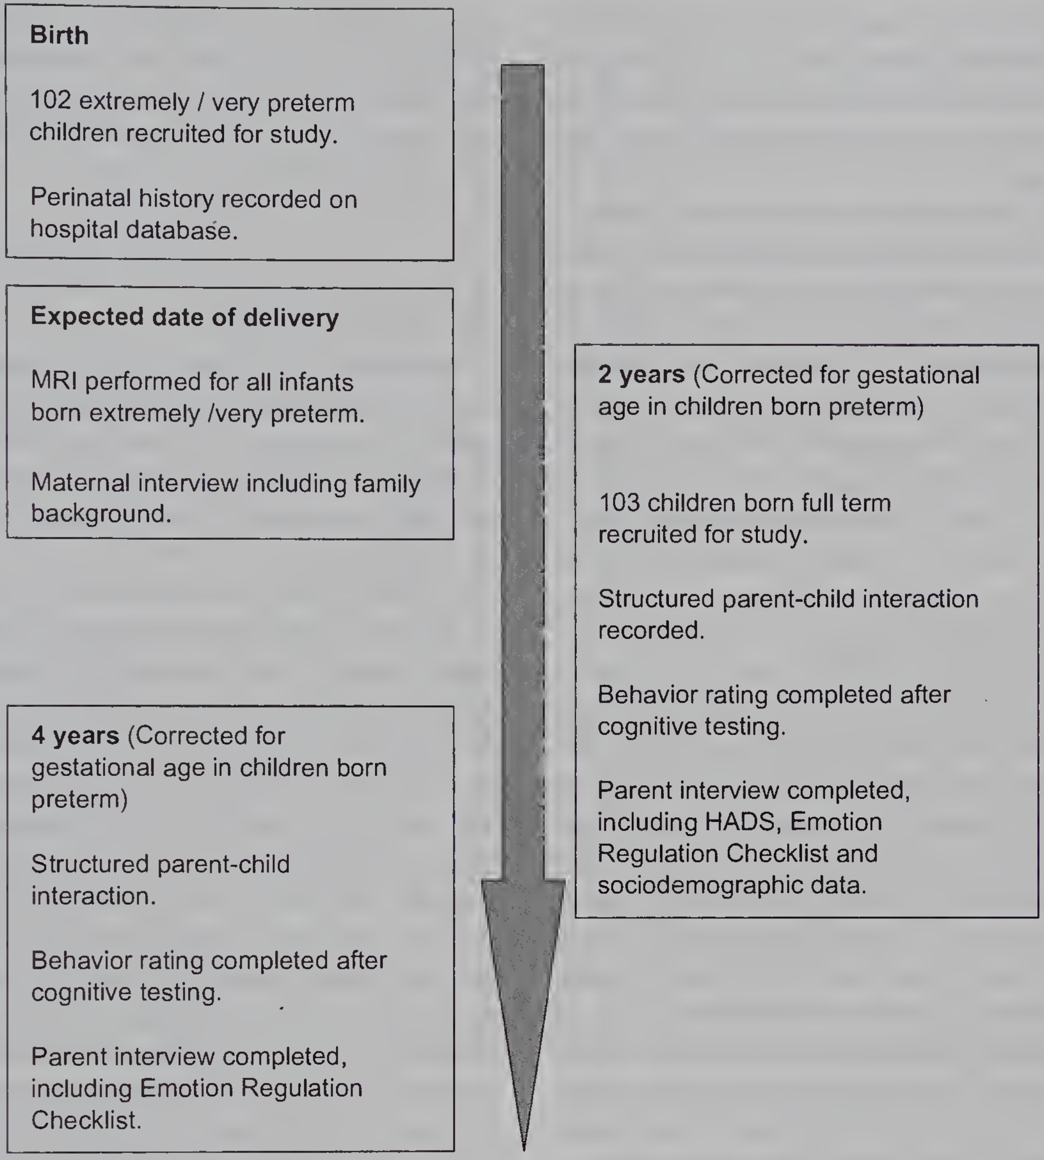
Emotional and Behavioral Regulation Measures

Observed child behavior during parent–child interaction. At ages 2 and 4 years, at the beginning of each child's developmental assessment, a structured parent–child play interaction took place. This was videotaped for subsequent coding and analysis. This activity was described to parents as an opportunity to see how their child learned to solve problems with the support of someone familiar. Before beginning the activity, each problem-solving task was explained to the parent and they were shown how to complete the task while another researcher distracted the child with a toy. Parents were instructed to introduce and complete each task one at a time and to allow their child a few minutes to explore each task by themselves before offering assistance. Following this time, parents were told that they could provide whatever assistance they deemed necessary to help their child complete the task. Once the parent indicated that they understood the procedure, the researchers left the room and video recording began.

Three different age-appropriate problem-solving tasks were used at each assessment point. Tasks were selected to be challenging for the child and were ordered, based on piloting data, to increase in difficulty. The tasks used at both ages were similar in nature but differed in complexity to offer appropriate developmental challenge. At age 2 years, children and their parents completed three activities. The first was a color-matching puzzle, which involved matching 12 colored disks to their corresponding color on a puzzle board. The second task required the child to move a sliding lid on the top of a two-holed (triangle and rectangle) posting box so as to place each shape in the corresponding posting hole. The third activity involved a more complex task using a clear, rectangular perspex box (Matas, Arend, & Sroufe, 1978). A small smiley-faced stamp was placed within the box, and the child had to place a weight on a wooden lever to lift the stamp and retrieve it.

At age 4 years, children completed four tasks. The first task was a simple, 10-piece jigsaw puzzle of a teddy bear. The second activity was a magnetic-letter board, requiring children to copy the word "flower" using magnetic letters. All letters of the alphabet were available, and children had to select those of the same color to match on the board. The third activity required children to copy a castle model using large Lego blocks, and the fourth was a bead-threading task in which children were required to reproduce a pattern of threaded beads of different colors and shapes. The activities were hidden with cloth covers so that parents could introduce each activity one at a time.

A range of child and parent behaviors were coded, based on these videotaped parent–child interactions. Raters coded child behaviors first and then rewound the tape to code parent behaviors. For each problem-solving task, four child behaviors were rated using



Birth

102 extremely / very preterm children recruited for study.

Perinatal history recorded on hospital database.

Expected date of delivery

MRI performed for all infants born extremely /very preterm.

Maternal interview including family background.

2 years (Corrected for gestational age in children born preterm)

103 children born full term recruited for study.

Structured parent-child interaction recorded.

Behavior rating completed after cognitive testing.

Parent interview completed, including HADS, Emotion Regulation Checklist and sociodemographic data.

4 years (Corrected for gestational age in children born preterm)

Structured parent-child interaction.

Behavior rating completed after cognitive testing.

Parent interview completed, including Emotion Regulation Checklist.

Figure 1. Overview of study design.

5-point Likert scales. These behaviors were based on previously used coding schemes and included positive affect, negative affect, persistence/sustained attention, and the quality of transition across tasks (Belsky, Jaffee, Sligo, Woodward, & Silva, 2005; Chase-Lansdale, Brooks-Gunn, & Zamsky, 1994; National Institute of Child Health and Human Development Early Child Care Research Network, 1999). *Positive affect* was coded on the basis of the intensity and duration of positive facial expressions (smiles and laughter), exclamations, and voice tone. *Negative affect* assessed the frequency and intensity of frowns, pouting, whining, crying, and signs of anger or frustration. *Persistence* was based on the level of attention and motivation the child showed while completing the task. Children who actively avoided completing a task were allocated low ratings, whereas those who worked persistently to complete a task were allocated the highest ratings. *Quality of a child's transition* between tasks was coded based on how smoothly a child moved from the completion of one problem-solving task to another. Children who refused to engage in new tasks or returned persistently to a previous task were rated lower on this scale. An overall mean rating for each child behavior was computed by averaging scores across the three tasks completed at age 2 years and the four tasks completed at age 4 years.

Two raters independently coded tapes using pencil-and-paper methods at age 2 years. Three raters independently coded tapes for the 4-year interactions. All observers were trained by the same clinical psychologist and were blind to infant perinatal history. Interrater agreement was assessed for 15% of tapes at 2 years and 20% at 4 years. Pearson product moment correlations between the two raters at age 2 years ranged from .68 to .90. Intraclass correlations were used at age 4 years because there were three raters at this age. Correlations for absolute agreement ranged from .83 to .90 for the four codes at age 4 years.

Complete video data were not available for 8 children at 2 years and 3 children at 4 years due to problems with recording quality or video recorder malfunction. These children were therefore excluded from analyses at the respective ages.

Tester ratings of child behavior during cognitive assessment. Children completed the Bayley Scales of Infant Development—Revised (Bayley, 1993) at age 2 years. At age 4 years, children completed an extensive battery of executive function tasks, as well as a four-subtest version of the Wechsler Preschool and Primary Scales of Intelligence—Revised (Wechsler, 1989). Cognitive and health outcomes of this cohort are reported elsewhere (Edgin et al., 2007; Foster-Cohen et al., 2007; Gray, Woodward, Spencer, Inder, & Austin, 2006; Woodward, Anderson, Austin, Howard, & Inder, 2006; Woodward, Edgin, Thompson, & Inder, 2005). Following cognitive testing at each age, two examiners completed consensus ratings of children's behavior based on an abbreviated version of the Behavior Rating Scale of the Bayley Scales of Infant Development at age 2 years. This scale included items assessing child positive affect, negative affect, initiative, attention, persistence, enthusiasm toward tasks, orientation to examiner, social engagement, and cooperation. Each item was rated on a scale ranging from 1 (*less observable*) to 5 (*more observable*). These measures were chosen based on the previous literature suggesting that children born preterm may have difficulties in these areas and because they were deemed to be developmentally relevant for both 2- and 4-year-olds. Examiners were blind to gestational age and clinical history but were not always able to remain blind to group status. A composite measure of tester-rated regulation was computed from the mean of these items. Cronbach's alpha coefficients for this nine item scale were .93 at age 2 and .90 at age 4 years.

Parent-rated self-regulation. During each assessment, parents completed a structured interview with a trained research nurse. A modified version of the Emotion Regulation Checklist (Shields & Cicchetti, 1997) was included in this interview. Scale items were reviewed by both a clinical and a developmental psychologist and were reworded to be appropriate for young children in New Zealand. The final checklist consisted of 24 items assessing the management and lability of emotions and tolerance to upset. Statements such as "is prone to disruptive outbursts of energy or excitement" and "responds positively to neutral or friendly attempts to interact with peers" were rated on a 3-point scale ranging from 1 (*not true*) to 3 (*certainly true*). Some of these items were reverse coded in order to provide a composite measure of emotion regulation, with higher scores reflecting a greater ability to manage one's emotion. For analysis purposes, scores were rescaled so that they were on the same metric (1–5) as observational measures. Cronbach's alpha coefficients for this scale were .69 at age 2 and .64 at age 4 years.

Infant Clinical, Neuroanatomical, and Family Background Measures

To examine the extent to which the development of self-regulation across the three study groups over the period from age 2 to 4 years was influenced by children's clinical history and sociofamilial experiences after birth, the following measures were included in this analysis.

Infant clinical and neurological characteristics. Measures of infant health and well-being included gender, birth weight, IUGR, twin birth status, chronic lung disease, antenatal steroid exposure, NEC, and PDA. In addition, at the time of their expected date of delivery, all infants born very preterm underwent MR imaging using a 1.5 T General Electric Signa System Scanner (GE Medical Systems, Milwaukee, WI). Infants were calmed, wrapped, and positioned in the scanner in a vacuum fixation pillow, which limited movement and allowed for scanning with no sedation. Two imaging modes were applied. These included (a) a three-dimensional Fourier transform spoiled gradient recalled sequence (1.5 coronal slices, flip angle 45°, repetition time 35 ms, echo time 5 ms, field of view 18 cm, matrix 256 × 256) and (b) a double echo (proton density and T2-weighted) spin echo sequence (DE; 3 mm axial slices, repetition time 3,000 ms, echo times 36 and 162 ms, field of view 18 cm, matrix 256 × 256, interleaved acquisition). The voxel volumes were 0.7 × 0.7 × 1.5 mm for the spoiled gradient recalled sequence acquisition and 0.7 × 0.7 × 3 mm for the spin echo acquisition. Full details of the scanning protocol have been reported in previous articles (Inder, Anderson, Spencer, Wells, & Volpe, 2003; Woodward et al., 2005).

MR scans were analyzed on five 3-point scales assessing (a) the extent of white matter signal abnormality, (b) periventricular white matter volume loss, (c) the presence of cysts, (d) ventricular dilation, and (e) thinning of the corpus callosum and reduced myelination. A pediatric radiologist, who was blind to the medical history of the infants, scored each scan. Each scan was then independently reviewed by another pediatric neurologist, with discrepant cases given a consensus rating. Interrater agreement was 95%. One child in the preterm group was unable to be scored. Based on their total cerebral white matter abnormality score, infants were divided into three groups. These groups included the following: no abnormalities (composite score 5–7, $n = 23$), mild abnormalities (composite score 8–10, $n = 54$), and moderate to severe abnormalities (composite score > 10, $n = 17$). Further details about the scoring of the MR data can be found in an online supplement to Woodward et al. (2006).

Measures of family social background and parenting. Five measures of children's social and family background were included in the analysis. The first was maternal age at birth. The second was SES, as measured by the Elly–Irving Socioeconomic Index (Elly & Irving, 2003). Families were assigned an SES level ranging from 1 (*professional*) to 6 (*unemployed*) based on the profession of the highest earning parent. This scale has been standardized for use with New Zealand families and has good predictive validity (Fergussen & Woodward, 2000). The third measure was maternal anxiety or depression as assessed by the Hospital Anxiety and Depression Scale (HADS; Zigmond & Snaith, 1983). This 14-item measure consists of statements such as "I feel as if I'm slowed down" and "I get sudden feelings of panic," which mothers rated on a scale of 0 (*never*) to 3 (*most of the time*). Scores were reverse coded where necessary and summed to produce a composite index of depression and anxiety. The HADS has been shown to have adequate reliability and validity (Herrmann, 1997; Mykletun, Stordal, & Dahl, 2001). Internal consistency, assessed using Cronbach's alpha, was .80 in this sample.

In addition to the child behaviors, two parenting behaviors, rated on the basis of the videotaped parent–child interaction obtained at age 2 years, were selected for inclusion in this analysis. These scales included parental sensitivity and intrusiveness and were rated on a 5-point Likert scale, where 1 represented a low degree of sensitivity/intrusiveness and 5 represented a high degree of these behaviors. *Parental sensitivity* provided a measure of the verbal and nonverbal support that a parent showed toward their child. Parents who showed supportive behaviors such as leaning in toward their child when they were having more difficulty, being involved and encouraging, providing assistance in a timely fashion, pacing the interaction so that the child remained engaged, or allowing the child to explore the puzzles while anticipating when they required more support were given higher ratings on this scale. *Parental intrusiveness* measured the extent of excessively or inappropriately controlling actions or commands. Parents who were directive in their instructions, who were interfering, or who tended to take over the completion of a task without allowing the child time to explore or tackle the tasks independently were rated higher on this measure. These measures were based on previously established schemes (Belsky et al., 2005). Interrater reliabilities, based on Pearson product moment correlations, were .84 for parental sensitivity and .68 for intrusiveness.

Finally, a measure of children's exposure to early intervention was also included. This measure was based on parent-reported intervention experience up to age 4 years. Only those children who attended early intervention beyond 6 months were considered to have received intervention, as a large proportion of children underwent monitoring for potential intervention prior to this age. Intervention was generally multidimensional and targeted at both motor and cognitive functioning.

Statistical Methods

Between-group differences in the medical and social characteristics of the very preterm, extremely preterm, and full-term groups were examined using analysis of variance (ANOVA) for continuous variables and the chi-square test of significance for categorical variables. Following this, data analysis was completed in three parts, corresponding to each study aim. First, ANOVA was used to examine mean differences on individual measures of regulatory competence across the three groups of children (extremely preterm, very preterm, and full term). In general, Kolmogorov–Smirnov tests on the data from these measures showed that distributions were skewed. Thus, these analyses were rerun using nonparametric Kruskal–Wallace tests. The results from these tests were consistent with those reported for the ANOVAs. This analysis was then extended to control for the effects of between-group differences in SES using analysis of covariance.

Second, in order to examine the extent to which a composite measure of children's regulatory competence across contexts might be created, bivariate Pearson product moment correlations were used to examine the concordance between multiple measures of regulation across the whole sample, the group of children born very/extremely preterm, and the group of children born full term at each age studied. Following this, principal components analysis (PCA) was used to create a regulation composite. Between-group differences in performance on this composite across the two time points studied were then examined using a repeated measures ANOVA.

Third, in order to examine the relationship between a number of social and medical factors and later regulation, a general estimating equation (GEE) regression model was fitted to the regulation composites across the two ages for the very preterm and extremely preterm groups only. This analysis included consideration of fluctuations in children's regulatory competence over time, while taking into account the correlations between repeated observations (Hanley, Negassa, Edwardes, & Forrester, 2003). A p value of .05 was used for significance testing, apart from the analysis for the final regression model, where a significance level of $p < .10$ was used to determine whether each predictor should be included in or excluded from the model.

Results

Characteristics of the Sample

Table 1 provides a descriptive profile of the clinical, social background and family characteristics of children in each study group. Inspection of Table 1 shows that decreasing gestational age at birth was associated with increased risks of medical complications, including lower birth weight ($p < .001$), IUGR ($p < .05$), moderate-to-severe cerebral white matter abnormalities ($p < .001$), chronic lung disease ($p < .001$), sepsis ($p < .001$), PDA ($p < .001$), and NEC ($p < .001$). Multiple births were also more common in the very preterm and extremely preterm groups ($p < .001$) as was exposure to early intervention ($p < .001$).

Consideration of the family social background characteristics of study children also revealed that children born extremely preterm or very preterm were characterized by higher rates of socioeconomic disadvantage ($p < .001$), maternal educational underachievement ($p < .01$), and maternal smoking during pregnancy ($p < .05$). There was also a tendency for mothers of these infants to have higher depression–anxiety scores than mothers of term-born control children at 2 years, although this did not reach statistical significance. Observation of parenting at age 2 years showed that parents of children born extremely preterm and very preterm appeared less adept at anticipating cues, responding to signals in a timely fashion ($p < .05$), and that they behaved more intrusively ($p < .01$) during problem solving.

Emotional and Behavioral Regulation at Ages 2 and 4 Years

Table 2 describes the early emotional and behavioral regulatory abilities of extremely preterm, very

Table 1
Infant and Family Characteristics of Children Born Extremely Preterm, Very Preterm, and Full Term

Mean (*SD*) parent-reported regulation	4.07[a] (0.52)	4.28 (0.58)	4.39 (0.39)	6.42	.002	.75; .25

Note. Effect size (d) comparing (a) extremely preterm and full-term groups and (b) very preterm and full-term groups based on Cohen's criteria: .2 = small, .5 = medium, and .8 = large.

[a] Mean score for extremely preterm group is significantly different from that for full-term group ($p < .05$). [b] Mean score for extremely preterm group is significantly different from that for very preterm and full-term groups ($p < .05$).

preterm, and full-term infants across a range of measures administered at age 2 years and then repeated at age 4 years. These measures included independent ratings of children's observed emotional behavior (positive and negative) and regulatory control during a 10- to 15-min structured parent–child interaction at the ages of both 2 and 4 years, tester ratings of children's emotional regulation during cognitive assessments, and parental ratings of children's emotional regulation on the Emotion Regulation Checklist. Associations between gestational age at birth and children's subsequent emotional and behavioral regulatory skills were examined using one-way ANOVA, with Tukey tests for honestly significant differences used for post hoc, between-group contrasts (e.g., extremely vs. very preterm). The results of this analysis are presented in Table 2 and show the following:

1. At age 2 years, significant associations were found between children's gestational age at birth and their subsequent persistence and sustained attention during a series of problem-solving tasks with their mother ($p < .05$), as well as their observed emotional regulation during testing ($p < .01$). Specifically, decreasing gestational age was associated with poorer emotional regulation, attention, and behavioral control across two independent observational assessments at age 2 years. There was also a tendency for children born at lower gestational ages to be characterized by lower levels of positive affect than term-born infants ($p < .10$). Post hoc Tukey tests showed that children in the extremely preterm group were significantly less likely than those in the full-term group to show persistence during the problem-solving interactions ($p < .01$). They were also rated by examiners as showing less regulatory competence during testing, relative to the full term ($p < .01$), group and there was a tendency for them to show less positive affect while engaging in problem solving ($p < .10$). Effect sizes for significant differences between the extremely preterm and full-term groups at this age were small to moderate (.36–.66), whereas those for the very preterm relative to the full-term group were small or negligible (.15–.36; Cohen, 1992). No significant associations were found between gestational age and children's observed negative affect and ability to transition between different tasks during play with their primary caregiver or in terms of parental perceptions of emotional regulation.
2. At age 4 years, a significant relationship was also found between gestational age and persistence

> and engagement ($p < .05$) during parent–child interaction. A significant relationship was also shown between gestational age group and tester-rated emotional regulation ($p < .05$). Additionally, there was a significant relationship between gestational age and parent-reported emotional regulation ($p < .01$). Post hoc Tukey tests showed that children in the extremely preterm group showed less persistence than both the very preterm and full-term groups across the problem-solving tasks ($p < .05$) and were rated by examiners as being less regulated during testing ($p < .05$). They were also rated by parents as having less ability to regulate their emotional responses and behavior than the full-term ($p < .01$) and, to a lesser extent, the very preterm ($p < .10$) group. Effect sizes for the differences between the extremely preterm and full-term groups were small to moderate (.30–.73), whereas those for the differences between the very preterm and full-term groups were generally negligible (.01–.24). No significant associations were found between gestational age and the extent of children's observed positive or negative affect or their ability to transition smoothly between tasks when interacting with a primary caregiver.

Given the significant differences in the socioeconomic backgrounds of the full-term and preterm groups, these analyses were rerun controlling for household SES. Findings from this analysis were consistent with those reported above, with all significant associations remaining even after taking family SES into account.

Collectively, these findings revealed a generally significant pattern of differences between children of varying gestational ages in their ability to regulate themselves during testing and in their persistence during interactions with their primary caregivers at ages 2 and 4 years. In addition, findings suggest that children born extremely preterm tend to be characterized by more pervasive dysregulation than their very preterm and full-term peers, with effect sizes for significant differences between extremely preterm and full-term children tending to be larger than those between the very preterm and full-term groups.

Development of Self-Regulation Between the Ages of 2 and 4 Years

The general pattern of associations between gestational age at birth and children's self-regulatory abilities shown in Table 2 raises the issue of how these skills may develop and change over time in children exposed to varying degrees of biological risk. This question is important because it may help clarify whether observed regulatory impairments reflect a persistent deficit in regulation, a transient delay, or a divergent developmental course for all or some children born preterm. This question was addressed by the following analyses.

First, we examined the extent to which the observational and parent report measures of children's emotional and behavioral regulation might reflect a common regulation factor at each assessment point. Such a composite measure would, theoretically, offer a more robust measure, spanning a range of salient aspects of children's emerging regulation observed across multiple contexts. Methodologically, such a composite would also enable a clearer examination of the development of regulation across time, as well as the factors influencing the development of children's regulatory competence over early childhood. This analysis was conducted in three steps. First, intercorrelations between measures at each time point and across time were examined. Most of these correlations were significant ($p < .05$), with evidence of both concordance across raters and situations, as well as some indication of stronger correlations between measures becoming evident with age, particularly with respect to parent reports of emotional regulation and independent ratings of child behavior during parent–child interaction.

Given the presence of significant associations between individual measures, scores of the full sample were subjected to PCA using an eigenvalue criterion of 1. Results from this analysis supported the presence of a single, common regulation factor at the ages of both 2 and 4 years. At age 2 years, the variance explained by this factor was 39.81%. Although parent-reported emotion regulation showed a much lower loading at age 2 years (.21) than did other factors (.58–.80), it was a stronger indicator of the factor at age 4 years (.53). At age 4 years, this factor explained 44.5% of the variance in outcome, with factor loadings ranging from .40 to .85. To assess whether this pattern differed for preterm and full-term children, the PCA was rerun separately for (a) children in the full-term group and (b) children in the preterm group. For the full-term group, a single factor solution was obtained, explaining 40.2% of variance at age 2 years and 47% at age 4 years. In the very preterm group, the parent-reported ratings on the Emotion Regulation Checklist comprised a separate factor at age 2 years, although all other measures had loadings of .55–.77. At age 4 years, all measures loaded consistently on one factor, which explained 43.35% of the variance in outcome. In general, these analyses provided statistical support for the formation of a composite measure of child regulation. Although for extremely and very preterm children, the parent report measure at age 2 years was not correlated with other measures, by age 4 years it was consistently associated with other measures. In addition, because it draws on the perspective of the parent, the inclusion of this measure provides for the description of regulatory competence across different contexts. Therefore, the decision was made to include it in our summary scores of regulatory competence.

To create the composite measures, children's individual scores on each of the measures collected across the two assessment time points were summed to form a composite measure of children's overall self-regulation at ages 2 and 4 years. Scores for child negative affect, as rated from the problem-solving activities with parents, were reverse coded so that all scores reflected a tendency toward better regulation of behavior and affect. Individual item scores were not weighted because all measures were scored on a common metric from 1 to 5. Cronbach's alphas for the scales were .68 at age 2 years and .71 at age 4 years.

Figure 2 illustrates the relationship between children's regulation at age 2 and 4 years for each of the three study groups. Examination of children's composite regulation scores over time showed that, across all groups, children's scores improved between the ages of 2 and 4 years. However, at both time points, children born extremely preterm were characterized by consistently lower scores than their full-term peers. In contrast, children in the very preterm group showed lower scores than full-term children at age 2 years but by age 4 years, achieved similar levels of self-regulation to children born full term. This pattern of findings was confirmed by a repeated-measures ANOVA with a 3 (gestational age group) × 2 (age assessed) design. Results demonstrated a significant age effect, $F(1, 182) = 236.25$, $p < .05$, showing that self-regulation improved across early childhood in all three groups. A significant group effect was also found, $F(2, 182) = 6.10$, $p < .01$, confirming earlier between-group differences in the ability of children to regulate themselves. Post hoc analyses confirmed that the extremely preterm group differed significantly from the full-term group in terms of their self-regulation across both ages ($p < .01$), although differences between the very preterm group and full-term group were at a trend level at age 2 ($p < .10$) and not significant at age 4 years ($p > .10$). In fact, at this age, post hoc testing showed that there was also a statistical trend toward lower performance in the extremely preterm group relative to the very preterm group ($p < .10$).

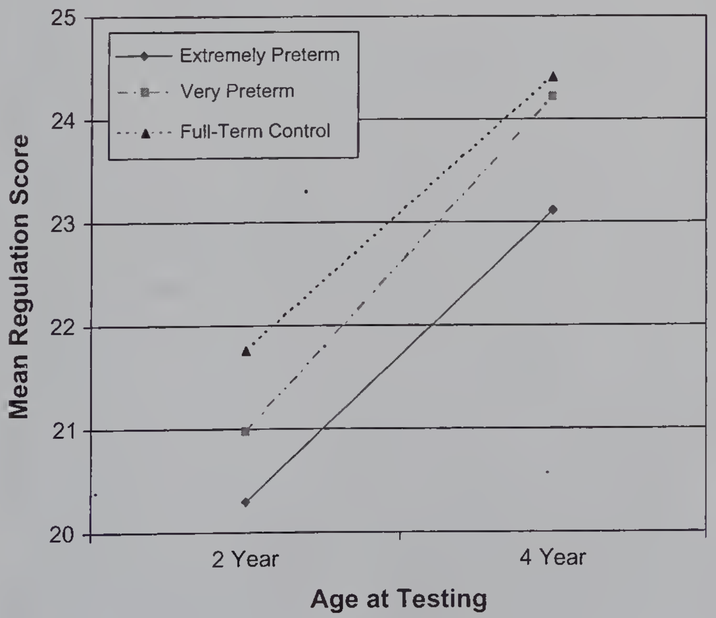

Figure 2. Development of regulation between 2 and 4 years in children born extremely preterm, very preterm, and full term.

Clinical and Sociofamilial Factors Influencing the Development of Self-Regulation in Children Born Preterm

The above findings suggest that decreasing gestational age at birth places children at increasing risk for regulatory difficulties, with extremely preterm children appearing to be especially vulnerable to persistent impairments relative to older preterm-born children and full-term-born children. However, it is also possible that these between-group differences in the development of self-regulatory skills among extremely and very preterm children may be partially or wholly explained by other factors correlated with gestational age at birth. For example, there is clear evidence from this (Table 1) and previous studies that children born extremely and very preterm often differ on a range of other clinical and sociofamilial factors that may also influence their longer term developmental outcome. Specifically, comparisons between the two preterm groups showed that children born extremely preterm had higher rates of perinatal medical complications, including lower birth weight ($p < .001$), chronic lung disease ($p < .001$), IUGR ($p < .10$), PDA ($p < .001$), sepsis ($p < .001$), NEC ($p < .05$), and cerebral white matter abnormalities on term MR imaging ($p < .001$). In addition, children born extremely preterm received a greater number of hours of intervention ($p < .05$). Although families of children born extremely preterm and very preterm did not differ in terms of SES, ethnicity, maternal age, smoking during pregnancy, or maternal depression, parents of children born extremely preterm appeared less sensitive to their children's cues ($p < .05$) and more intrusive ($p < .05$) during problem solving at age 2 years.

To examine the influence of these medical and social risk factors on preterm children's ability to regulate their emotions and behavior, a GEE regression model was fitted with regulatory competence at 2 and 4 years as the dependent variables. This method enabled the prediction of children's regulation across both time points within the same regression analysis. Each clinical and family background factor outlined in Table 1 was entered into the model in a forward and backward manner to test for significant relationships with later regulation. In addition, age was entered into the model to test for any differences across the two ages studied. The analysis was confined to the group of children born preterm. The final main effects model is shown in Table 3. As can be seen from this model, two perinatal factors, the presence of moderate to severe white matter abnormalities on term MR imaging ($p < .05$) and maternal antenatal steroid exposure ($p < .001$), were significantly related to later regulatory competence. Specifically, the administration of antenatal steroids played a protective role; however, moderate to severe white matter abnormalities on MR were associated with increased risk of poor regulation ($p < .05$). In terms of sociofamilial factors, parental sensitivity at age 2 years was an important independent predictor of children's later regulatory competence ($p < .05$). Finally, age was also found to be a significant predictor of children's regulation ($p < .001$), supporting earlier findings that children's regulatory abilities improved from 2 to 4 years of age. No significant interactions were found between each of the covariates and age, suggesting that these influences were not age dependent but were predictive of self-regulation across both ages.

Table 3
Predictors of Regulation in Children Born Extremely Preterm and Very Preterm at Ages 2 and 4 Years

	β	*SE*	χ^2	*p*
Extremely preterm birth	0.48	0.47	1.03	.31
Moderate to severe white matter abnormalities (term)	−1.62	0.63	6.54	.01
Antenatal steroids (birth)	1.44	0.47	9.43	.002
Maternal supportive presence during problem solving (2 years)	0.98	0.26	14.20	< .001
Time (2 or 4 years)	1.65	0.14	143.06	< .001

Discussion

The present study extends on previous research concerned with the impact of preterm birth on children's social and emotional development. Existing studies have primarily focused on the outcomes of school-aged children and adolescents born preterm, with little consideration given to the early development of emotional and behavioral competence in this high-risk population. Furthermore, little consideration has been given to the role of gestational age at birth, particularly extreme prematurity, or the explanatory role of other biological and sociocontextual factors. This prospective longitudinal study addressed these important gaps by examining the early emotional and behavioral regulation of children born extremely preterm, very preterm, and full term during early childhood. Strengths of the study included the relatively large sample size, the use of a multimethod measurement approach to the assessment of regulation, the use of repeated measures over time, inclusion of neuroanatomical MR measures, and detailed observational and parent report measures of children's social and familial experiences during infancy and early childhood. The major study findings are discussed below.

Extending on previous research demonstrating emotional and behavioral disturbances in older children born very preterm (Botting et al., 1997; Breslau et al., 1996; Klebanov et al., 1994; McCormick et al., 1996; Sykes et al., 1997), this study revealed the presence of pervasive differences between toddlers and preschool children born extremely preterm, very preterm, and full term on a range of measures of early emotional and behavioral development. At age 2 years, children born extremely preterm showed poorer emotional and behavioral regulation during cognitive testing and were less persistent in completing a series of problem-solving tasks. A generally similar pattern of emotional and behavioral differences emerged at age 4 years. However, by age 4 years, parents of children born extremely preterm were also more likely to report difficulties in emotional regulation, perhaps indicating that these difficulties were becoming more apparent to parents as children matured and parental expectations increased. Ratings of positive and negative affect during problem solving with parents did not differ significantly between groups. This may reflect the nature of the task, which was designed to be enjoyable and thus not particularly stressful for children or parents, perhaps resulting in fewer negative behaviors than a more structured and demanding task such as a cleanup task.

There is some overlap between these findings and those of studies examining the neurobehavioral outcomes of young children born very preterm. Based on experimental and observational measures, several studies have indicated that attention is an area of difficulty for children born very preterm (Caravale, Tozzi, Albino, & Vicari, 2005; Rose, Feldman, Wallace, & McCarton, 1989; Vicari, Caravale, Carlesimo, Casadei, & Allemand, 2004). For example, Landry and her colleagues (Landry & Chapieski, 1988; Landry et al., 1996) found that children born very preterm with a high degree of perinatal risk were less able to shift their attention effectively from one toy to another when examining toys alone or during interaction with their parents at age 6 months. In the present study, there were no differences in children's ability to transition from one task to another. Instead, children differed in the levels of persistence or sustained attention they showed during problem solving. Studies that have examined executive abilities in older children born preterm have also produced conflicting results regarding the specific areas of attention that may be disrupted, with some suggesting that sustained attention and inhibitory control may be areas of difficulty (Bohm, Smedler, & Forssberg, 2004; Katz et al., 1996; Korkman, Liikanen, & Fellman, 1996), whereas others indicate that attentional flexibility or shifting may be impaired (Bayless & Stevenson, 2007).

There is some possibility that different attentional impairments may become more apparent at different developmental stages, thereby explaining some of the variation in findings. However, these differences in findings may also be related to the paradigms employed. In this study, we only recorded quality of transition between tasks. We did not examine the number of times that children's attention shifted to different toys within each of the tasks. Also, although Landry and Chapieski (1988) found that children at high medical risk made fewer shifts between toys, they also found that children spent less time engaged with toys overall, suggesting that these children may not have shifted attention simply because their attention was focused elsewhere. In this case, it is difficult to clearly separate out the different facets of attention. With executive function becoming a popular area of interest for developmental psychologists and more precise tools for the measurement of attention emerging, these issues should be resolved. Regardless, this study is consistent with earlier studies of children born preterm in suggesting that difficulties in the regulation of attention and emotion are apparent at an early age (Garcia Coll et al., 1988; Lowe, Woodward, & Papile, 2005; Ohgi, Takahashi, Nugent, Arisawa, & Akiyama, 2003; Segal et al., 1995).

Examination of the development of children's behavioral and emotional regulation between the ages of 2 and 4 years showed that, across all groups, children showed developmental gains in overall regulation. Among the two high-risk groups (very preterm and extremely preterm), improvements were most marked in the older gestation, very preterm group. In contrast, children born extremely preterm, although showing developmental gains, continued to score significantly less well than their full-term peers. Continued follow-up of these children to school age will be important to help clarify the longer term implications of these findings.

These between-group differences in the development of self-regulation raise the important question of why some children born preterm, especially those born at lower gestational ages, tend to fare less well than others. An examination of the extent to which between-group differences in the development of regulation among children born extremely and very preterm could be explained by a range of medical and social factors correlated with gestational age revealed that both biological and sociofamilial factors made important contributions. Medical factors that emerged as important for the development of later regulation in this study were maternal antenatal steroid exposure, which was associated with better regulation, and moderate to severe white matter abnormality, which was associated with a poorer outcome. The finding of increased regulatory competence in children whose mothers were administered antenatal steroid therapies is intriguing and warrants further replication and investigation.

Once the presence of white matter abnormality was statistically controlled for, the effect of gestational age was no longer significant. This suggests that it may not be extreme prematurity per se that places these infants at risk for observable regulatory difficulties. Rather, findings suggest that cerebral white matter abnormalities, including white matter volume loss, cystic abnormalities, and immature patterns of myelination, may place constraints on the development of regulation. These findings are largely consistent with those of McGrath et al. (2005), who found that children born preterm with no medical or neurological complications showed similar levels of attentional regulation to their full-term peers. In contrast, those who were characterized by higher levels of neurological and medical risk showed greater impairments in attentional regulation. An advantage of the present study is that we examined independent risk factors in determining outcome, as opposed to relying on a composite medical risk score. This allowed us to isolate early neurological abnormality as being individually important for later regulatory development. Indeed, the present study contributes to a growing body of literature showing that early cerebral abnormalities, as determined by MR, may be a sensitive predictor of later impairment in children born very preterm (Peterson et al., 2003; Stewart et al., 1999; Woodward et al., 2006).

As others have noted (Nadeau et al., 2003; Taylor, Minich, Bangert, Filipek, & Hack, 2004), it does seem that the neurological effects of being born very early in these smallest infants have ongoing implications for longer term brain and behavioral development. The principal region of injury in the premature infant is the periventricular zone, which is an important area of neuronal integration and cortical projection. Damage in this region has been associated with disrupted myelination and organization of important fiber tracts connecting subcortical and cortical regions (Counsell et al., 2003; Huppi et al., 2001). As the brain becomes more integrated and there is increased modulation of lower level thalamic and cingulate processes by higher level frontal areas, children gradually develop a better ability to inhibit inappropriate responses, flexibly orient their attention, and organize their emotional responses (Diamond, 2002; Posner & Rothbart, 2000; Thompson, 1994). It may be that the disruption of neural development, caused by early insult or alterations to white matter tracts, interrupts the integrated coordination of these processes, thereby hindering children's ability to regulate effectively.

In addition to biological factors, the extent to which parents were responsive and sensitive to the needs of their child was also an important predictor of regulatory competence. Findings showed that parents of extremely preterm children had more difficulty scaffolding the interactions around cues from their children and providing well-timed support. Rather, they tended to become more intrusive during problem solving at age 2 years. These findings are consistent with mainstream developmental studies highlighting the importance of parental sensitivity for child cognitive and social development, as well as studies of children born at high biological risk (Landry, Smith, & Swank, 2003, 2006). Because ratings of parental and child behavior were taken during an interactive task, the direction of these effects is not clear. It is likely, however, that parent and child characteristics are interacting in a bidirectional manner. Children who have difficulties regulating their arousal and affect will require a higher degree of facilitation, soothing, and calming by parents. Coupled with this, signals from these children may be more ambiguous. For instance, children born very preterm have been found to exhibit more mixed cues with their caregivers (Eckerman, Hsu, Molitor, Leung, & Goldstein, 1999). Parents may react by becoming more intrusive in order to evoke a response from the child. This may be overstimulating for a child who is already trying to compensate for disrupted homeostasis, thereby setting up aversive social interactions for both parties. This will have ongoing effects on the development of the mutually rewarding relationship between parent and child.

Difficulties in the regulation of affect and attention have a number of implications for ongoing development. Subtle difficulties in regulation and emotional control may well become more apparent with the complex and challenging demands of the classroom, impacting on learning, self-esteem, and social development. Thus, early regulatory support may be an important target area for early intervention. Some support for this exists in the Newborn Individualized Developmental Care and Assessment Program, an intervention aimed at regulating arousal and improving signal recognition (i.e., sensitivity) of parents of compromised preterm babies. This intervention showed discriminate effects on later child behavior and quality of mother–child interaction (Kleberg, Westrup, & Stjernqvist, 2000). Furthermore, new exciting findings show that these changes may be accompanied by improved neurobehavioral functioning but also more mature frontal brain structure development (Als et al., 2004).

Although this study had a number of methodological strengths, including the use of multiple measures across time, a major challenge with this, as with other similar studies of very young children, is the lack of well-validated measures of early self-regulation. Relatedly, the need for longitudinal measures repeated across time possibly obscures important changes in development. It is possible that aspects of self-regulation applicable at age 2 years may become less salient with age. It may be that 2-year-olds are more likely, in general, to show extreme levels of affect. By age 4 years, such difficulties may manifest more in the regulation of motivation and attention, constructs that clearly differentiated children at this age. Further assessment of more specific and subtle behavioral differences that reflect poor regulation at various ages as well as the development of measures that can capture these differences remains an ongoing challenge for developmental research.

Nonetheless, this study does provide initial evidence of early and stable deficits in self-regulation during early childhood among children born preterm. It also highlights the importance of both neurological and social influences in accounting additively for differences in the self-regulatory abilities of children born extremely preterm, very preterm, and full term. Neonatal strategies aimed at minimizing the neurological impacts of being born too early and early intervention strategies that support parent's ability to support the developmental needs of their infants in a sensitive manner are likely to be important in reducing ongoing behavioral risks. Although it represents a significant step toward understanding the specific mechanisms and processes that lead to poor outcomes after preterm birth, future research through longer periods of follow-up is needed to ascertain the relevance of self-regulation, in relation to other developing skills and capacities, for long-term cognitive and socioemotional development in this vulnerable population.

Neighborhood Poverty and Early Transition to Sexual Activity in Young Adolescents: A Developmental Ecological Approach

Véronique Dupéré and Éric Lacourse

Tufts University

Richard E. Tremblay
Université de Montréal

This study examined how the link between neighborhood poverty and the timing of sexual initiation varies as a function of age, gender, and background characteristics. A sample of $N = 2,596$ predominately White Canadian adolescents from the National Longitudinal Survey of Children and Youth was used. Sexual initiations occurring between 12 and 15 years old were considered. Results showed that younger adolescent females who lived in poor neighborhoods and who had a history of conduct problems were more likely to report early sexual activity. Peer characteristics partly accounted for this susceptibility. Among adolescent males, no direct neighborhood effects were found, but those who had combined risks at multiple levels appeared more vulnerable. The theoretical and practical implications of these findings are discussed.

For many adolescents, sexual experimentation includes navigating the transition to first heterosexual intercourse, an event that becomes relatively common by the end of adolescence (Darroch, Frost, Singh, & Study Team, 2001). Although this transition becomes normative by middle to late adolescence, a small group of adolescents experience it much sooner. In particular, about 5% have had sex at 12 years of age in the United States; this rate gradually rises to around 10% at age 13 and 19% at age 14 (Albert, Brown, & Flanigan, 2003). Compared with later initiators, early initiators are much more likely to contract sexually transmitted diseases, undergo unwanted teen pregnancy, and report involuntary sexual experiences (e.g., Albert et al., 2003; Kaestle, Halpern, Miller, & Ford, 2005). Reports of such negative experiences decrease sharply for those transitioning in later adolescence. Despite the significance of sexual initiation in early adolescence, a recent review noted that its determinants have been understudied (Albert et al., 2003). This is problematic because the processes at play in older adolescents do not automatically apply to their younger peers. Just as the consequences of sexual activity dramatically change as adolescents mature, developmentally oriented researchers proposed that its determinants must also fluctuate at different developmental stages (Whitbeck, Yoder, Hoyt, & Conger, 1999).

In this study, we propose that both developmental (i.e., age) and contextual (i.e., neighborhood and peers) factors need to be considered simultaneously to adequately understand the determinants of the timing of sexual initiation. Adolescence is a period of intensified participation in larger social contexts outside the home, such as neighborhoods and peer groups, and these contexts are thought to exert powerful influences upon adolescent development, including sexuality (Browning, Leventhal, & Brooks-Gunn, 2004). The current study adopts an ecological, developmental approach to examine the timing of young adolescents' sexual initiation. That is, longitudinal data are used to explore how the relationship between neighborhood poverty and sexual initiation and hypothesized mediators (i.e., peer characteristics) vary with age among adolescent males and females. In addition, the moderating role of neighborhood circumstances on family and individual risk factors is examined.

This study was based on the doctoral dissertation of the first author, who was supported by a scholarship from Social Sciences and Humanities Research Council of Canada. The authors wish to thank Eric Dion and anonymous reviewers for comments on previous drafts. The research and analysis are based on data from Statistics Canada, and the opinions expressed do not necessarily represent the views of Statistics Canada.

Neighborhood Disadvantage and Early Transitions to Sexual Activity: Potential Moderators

Ecological models of human development suggest that the neighborhood environment is an important context for development (Bronfenbrenner, 1979). Correspondingly, studies have repeatedly found a link between neighborhood disadvantage and a number of risky adolescent sexual outcomes, such as inconsistent contraceptive use or teenage childbearing (Baumer & South, 2001; Leventhal & Brooks-Gunn, 2000). In contrast, studies investigating the link between neighborhood disadvantage and *timing* of sexual initiation have produced mixed results. Some found independent effects of neighborhood structural characteristics (i.e., poverty) over and above other important determinants (e.g., Browning et al., 2004; Ramirez-Valles, Zimmerman, & Juarez, 2002), whereas others did not (e.g., Baumer & South, 2001; Upchurch, Aneshensel, Sucoff, & Levy-Storms, 1999). Sample differences in terms of participants' characteristics, notably age and gender, might explain these inconsistencies.

Theoretical and empirical considerations suggest that the association between neighborhood disadvantage and sexual initiation could vary as a function of age. The developmental model proposed by Whitbeck et al. (1999) argues that exposure to nonnormative social contexts, such as deviant peers, should predict transitions occurring in early adolescence when the transition is clearly nonnormative and gradually lose predictive power as adolescents mature and the transition becomes more normative. Although they did not explicitly discuss neighborhood factors, their reasoning suggests that neighborhood disadvantage could be associated with sexual initiation in early adolescence, but not necessarily at later ages, given that neighborhood effects are often interpreted as a consequence of exposure to neighborhood deviant peers (Baumer & South, 2001). Also, younger teens may be especially susceptible to peer pressure and peer norms (Brooks-Gunn & Furstenberg, 1989). Empirical evidence indirectly supports the hypothesis of age-graded neighborhood effects on sexual initiation because significant effects have tended to be observed in comparatively younger samples. For instance, Browning et al. (2004) obtained significant neighborhood effects when modeling transitions occurring between 11 and 16 years old, whereas others did not, in samples followed throughout adolescence and into early adulthood (Baumer & South, 2001).

Gender is also likely to moderate the association between neighborhood disadvantage and early sexual activity. If sexual activity represents a departure from the norm for early adolescents, it is especially the case for females. Norms tend to recommend chastity for adolescent females, whereas sexual experimentation is often tacitly encouraged in males (Benda & DiBlasio, 1994). Echoing these diverging norms, sexually active adolescent females are more likely to be labeled negatively by their peers and to express remorse and regrets regarding their early sexual experiences, as compared with adolescent males (Dickson, Paul, Herbison, & Silva, 1998; Graber, Brooks-Gunn, & Galen, 1998). Because social norms tend to disapprove early sexual activity more strongly among adolescent females, exposure to more permissive norms might be especially influential for them. Empirical results suggest that in disadvantaged neighborhoods, young adolescent females are more likely to be exposed to alternative cultural scripts regarding sexuality (Harding, 2007). For instance, Harding (2007) found that in disadvantaged neighborhoods, a sizable minority of adolescents tend to view adolescent pregnancy in a positive light, whereas in more advantaged neighborhoods, there is a general consensus to view adolescent pregnancy as a negative event. Adolescent females appear especially sensitive when exposed to such alternative scripts. Indeed, exposure to peers having more permissive attitudes and behaviors toward sexuality has been found to predict entry into sexual activity for adolescent females but not for adolescent males (Billy & Udry, 1985). For this reason, adolescent females' sexual behavior could be generally more susceptible to neighborhood effects.

On average, adolescents living in poor neighborhoods are at an increased risk of being exposed to alternative cultural scripts regarding sexuality (Harding, 2007), but there is certainly a great deal of individual variability in the degree and intensity of exposure. Mounting evidence shows that key family and individual characteristics modulate neighborhood effects. At the family level, low socioeconomic status (SES), family disruption, and residential instability are factors likely to increase exposure to neighborhood peers with more permissive attitudes. For instance, single parents tend to have fewer resources to exert effective supervision than two-parent families and inconsistent supervision is more strongly associated with early sexual activity for adolescents living in disadvantaged neighborhoods (Browning, Leventhal, & Brooks-Gunn, 2005). Also, residentially unstable adolescents are at risk of making new deviant friends when they move into a new neighborhood and this, in turn, increases the likelihood of early initiation (South, Haynie, & Bose, 2005). This association could be especially strong among adolescents moving into a disadvantaged neighborhood. At the individual level, neighborhood disadvantage might also exacerbate the accelerating impact of early pubertal development and conduct problems, two characteristics associated with early sexual activity (Browning et al., 2004). Indeed, neighborhood disadvantage increases the chances that such predisposing individual characteristics actually translate into problem behaviors (e.g., Obeidallah, Brennan, Brooks-Gunn, & Earls, 2004). Thus, there are good reasons to consider family and individual characteristics not only as statistical controls but also as potential moderators of neighborhood effects.

Neighborhood Poverty and Early Sexual activity: A Peer Mediation Model

So far, we have argued that neighborhood disadvantage may be associated with early sexual activity and that this association may vary as a function of individual and family characteristics. This section now addresses potential explanations for neighborhood effects. Theoretical and empirical considerations suggest that "peers may be the primary agent through which community socialization adversely affects adolescents" (Leventhal & Brooks-Gunn, 2000, p. 327). Previous research suggests that adolescents are more likely to affiliate with deviant peers if they live in a disadvantaged neighborhood (Brody et al., 2001) apparently because of a reduced collective capacity to supervise and control youth groups in these contexts (Sampson, Morenoff, & Gannon-Rowley, 2002). The proposition that peer processes are important mediators of neighborhood effects has been repeatedly supported in the delinquency literature (e.g., Ingoldsby et al., 2006; Simons, Johnson, Beaman, Conger, & Whitbeck, 1996).

Recent findings suggest that peer factors may play a primary mediating role for sexual risk taking as well. When examining the mediating role of a host of potential explanatory processes for neighborhood effects on adolescents' sexual behaviors, Baumer and South (2001) found that the sole peer characteristic that they considered, a composite measure of peer attitudes and behaviors, was the only variable with a significant, although partial, mediating effect. The present study builds on these findings by considering the mediating role of peer deviance and of involvement with an older sexual partner. These characteristics were selected because evidence suggests that they are associated with both neighborhood disadvantage and early sexual activity. We briefly outline this evidence below.

Affiliation with deviant peers is one of the prominent risk factors for early sexual initiation (e.g., French & Dishion, 2003), most likely because deviant peers provide a pool of willing partners and cultivate a sense that early sexual activity is desirable. Deviant peer affiliation could mediate neighborhood effects, given that neighborhood disadvantage is a risk factor for deviant peer affiliation (e.g., Brody et al., 2001). Involvement with an older partner is another potential explanatory factor, especially for adolescent females. Indeed, although getting involved with an older partner increases the risk of early sexual activity for both adolescent males and females (Marin, Coyle, Gomez, Carvajal, & Kirby, 2000), this situation is rare among adolescent males and affects a much greater proportion of females (Halpern, Kaestle, & Hallfors, 2007), especially young, early-maturing females (Manlove, Ryan, & Franzetta, 2007). This may be attributable to the attractiveness of young, physically developed adolescent females to older males (Caspi, Lynam, Moffitt, & Silva, 1993; Halpern et al., 2007). Certain contexts, such as disadvantaged neighborhoods, may increase the likelihood that physically mature adolescent females affiliate with older peers and engage in risky behaviors (Obeidallah et al., 2004). Thus, differential exposure to older partners and deviant peers could potentially explain neighborhood effects on the timing of sexual initiation.

In this study, a developmental, ecological perspective is adopted to examine young adolescents' transitions to first sexual activity. A representative sample of Canadian adolescents is used to explore how the relationship between ecological risk factors (neighborhood disadvantage), hypothesized mediators (peer characteristics), and sexual initiation varies with age. In addition, the moderating effects of other factors that could alter adolescent susceptibility to neighborhood circumstances, such as gender and individual characteristics, are considered. We hypothesize that peer characteristics would at least partly account for this vulnerability.

Method

Sample

The National Longitudinal Survey of Children and Youth (NLSCY) is a nationally representative, prospective study of Canadian children and adolescents (Statistics Canada, 2005). The sample design is a clustered probability sample of private households within the 10 Canadian provinces, excluding children living in remote areas, institutional settings, and on First Nations reserves. The NLSCY was launched in 1994–1995, with follow-up surveys conducted every 2 years thereafter. Initially, 13,439 households of 15,579 identified as having at least one dependent child, ages newborn to 11 years, agreed to participate in Cycle 1 of the study. Within each household, up to two children per family were selected to participate in the longitudinal survey, resulting in a longitudinal sample of 16,903. In each of the survey households, the "person most knowledgeable" about the child was interviewed. In virtually all cases, this person was a parent and in most cases the mother and hereafter is referred to as such. From 10 years old on, children were also asked to complete self-report questionnaires.

This study uses data from the first five data collection cycles (1994–1995 to 2002–2003). Because questions about age at sexual initiation were consistently included in the survey only for participants of at least 16 years old, the subsample used includes older NLSCY participants who were at least 16 years old in Cycle 5 (i.e., participants who were between 8 and 11 years old in Cycle 1, in 1994–1995). This represents about 5,000 adolescents. Of these, only those who participated in all cycles of data collection were selected. A total of 2,960 participants met this inclusion criterion, representing a retention rate of about 60% for an 8-year span. Of that number, 19 cases who reported sexual initiation before age 12 were excluded. Another 23 participants were excluded due to data inconsistencies. Finally, one child per household was selected at random to avoid within-family clustering. Thus, the final sample size is $N = 2,596$. The sample was evenly distributed across both genders and more than 90% of the participants were Whites. The remaining participants were composed mainly of First Nations children and children of Asian or African descent.

To take attrition into account as well as the stratified sampling of the NLSCY, all analyses were conducted using normalized longitudinal survey weights. The use of weights helps preserve the representativeness of the sample despite survey dropout, but it does not eliminate potential bias associated with partial nonresponse. Partial nonresponse occurs when participants fail to answer some of the survey questions. In this study, the rate of partial nonresponse varied between 0% and 7% for parent-reported variables and between 3% and 15% for self-reported variables (by design, some self-reported variables had a higher rate of missing data; for instance, those who were still virgins in Cycle 5—i.e., at 16–17/18–19 years old—were not asked about the age of first sexual partner). Multiple imputation was used to handle partial nonresponse (Allison, 2001). Multiple imputation is among the best methods currently available for reducing possible bias due to partial nonresponse, whereas taking into account imputation uncertainty. In this study, partial nonresponse was treated through the creation of five complete data sets obtained through multiple imputation (SAS MI procedure). Regression analyses were performed on each imputed data set separately, and the parameter estimates obtained in each set were recombined, resulting in a final, single set of estimates. The analyses were also repeated using simple listwise deletion of cases with missing data, and the main conclusions of the present study remained essentially unchanged.

Measures

Transitions to first sexual activity occurring during the first half of adolescence were considered (12–15 years old). Family (family structure, SES, and residential instability) and individual (behavior problems and pubertal development) predisposing factors were measured in late childhood (10–11 years old) and were thus antecedent to the outcome. Neighborhood poverty was measured concurrently during early adolescence (12–15 years old). Peer deviance was also measured concurrently, at 12–13 and 14–15 years old, whereas age at sexual intercourse and age of first sexual partner were measured retrospectively (16–17 or 18–19 years old). A summary of the measurement time points for each variable is provided in Table A1 in the Appendix.

Late Childhood Family and Individual Risk Factors

Family SES was measured through an index computed by Statistics Canada (Willms & Shields, 1996). Five standardized variables were combined to calculate family SES, including mothers' and fathers' educational attainment, mothers' and fathers' occupational prestige (classified according to the Standard Occupational Classification System), and household income. In this sample, the index ranged from −3.5 to 2.8 ($M = 0.0$, $SD = 0.8$). *Intact family status* represented those (73%) who lived with two biological or adoptive parents. *Residential instability during childhood* was also considered. The number of childhood relocations before the child reached age 10–11 varied from 0 to 15. This variable was recoded into a dichotomous variable contrasting those who had moved fewer than five times with those who had moved five times or more (11%).

Conduct problems were assessed with nine self-reported items representative of the three symptom domains listed in the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV)* for conduct disorders, that is, physical aggression (bullying, fighting, attacking, kicking, or biting), destruction of property, deceitfulness or theft (vandalism and stealing), and serious violations of rules (running away, truancy, and staying out all night). Following the *DSM-IV* classification rules, those who reported that they had engaged in at least three of these behaviors in the past 12 months (13%) were considered at risk. *Early pubertal development* was measured with three gender-specific items pertaining to change in physical development markers: body hair, breast development and menstruation for adolescent females, and body hair, facial hair, and voice change for adolescent males. All questions were answered on a 4-point scale (0 = *no change yet* to 3 = *change completed*), except for menstruation, which was dichotomous. For items measured on a 4-point scale, responses were rescaled to range from 0 to 1. Then, total scores were computed and normalized by gender and age. Those with higher scores were more physically developed than their same-gender peers in late childhood.

Neighborhood Poverty

Links to the 2001 Canadian Census were made to assess the neighborhood poverty status associated with participants' main place of residence. The dissemination area (DA) was the geographic unit used to approximate the neighborhood environment. The DA has a population range of about 400 – 700 individuals (Puderer, 2001), which roughly corresponds to U.S. Census block groups. All DAs with 20% or more residents under Statistics Canada's low-income cutoff were considered as poor neighborhoods. About a quarter of participants resided in a poor neighborhood.

Peer Characteristics

Peer deviance was estimated with a single item asking the mother how often their child "hung around with kids who are frequently in trouble." Those who exhibited this behavior often or sometimes were considered at risk (12%). This single item was retained because unfortunately, other items measuring peer deviance were not consistent across data collection cycles. Participants who were sexually experienced were asked retrospectively about the *age of their first sexual partner*. For those who answered this question in more than one cycle, the first valid age reported was used. In virtually all instances, reported age of partners ranged between 12 and 25 years old. A dichotomous variable distinguishing those who had a first partner at least 3 years older than themselves at time of sexual initiation was created. As expected, adolescent females were much more likely to have been sexually initiated with an older partner as compared to adolescent males, especially among younger adolescents. For instance, among adolescent females who became sexually initiated before 16 years old, 34% reported first intercourse with an older partner, whereas this rate dropped to 4% for adolescent males. These proportions are similar to those of other studies showing that around a third of sexually initiated adolescent females have a first sexual experience with a partner at least 3 years older, whereas this proportion is much lower among males (Manlove et al., 2007).

Outcome: Timing of First Consensual Sexual Intercourse

The observation window for the outcome covered the first half of adolescence (12 – 15 years old). The timing of entry into sexual activity was measured retrospectively by asking participants: "Have you ever had consensual sexual intercourse?" And, for those who answered positively: "How old were you when you first had consensual sexual intercourse?" For those who answered the question about age at sexual initiation in more than one cycle, the first valid age reported was used. Otherwise, the answer obtained in the last available wave of data collection was used (Cycle 5). It is important to note that sexual intercourse was not explicitly defined in the questionnaire. Thus, the measure is subject to interpretation bias and does not allow distinctions between sexual initiations occurring between same- and other-gender partners. The distribution of age at first intercourse was not significantly different for adolescent males and females, $\chi^2(4, N = 2{,}596) = 2.97$, $p = 0.56$, a result consistent with other recent studies using representative samples of Canadian adolescents (Hansen, Mann, McMahon, & Wong, 2004). As expected, the proportion of adolescents becoming sexually initiated increased steadily with age, from less than 2% at 12 years old to up to 15% at 15 years old. These proportions are consistent with those obtained in other representative samples of Canadian adolescents (Hansen et al., 2004; Maticka-Tyndale, McKay, & Barrett, 2001).

Results

Descriptive Statistics

Table 1 shows the distribution of the risk factors as a function of neighborhood poverty. Adolescents living in poor neighborhoods were more likely to come from low-SES, nonintact, and residentially

Table 1

Descriptive Statistics as a Function of Neighborhood Context[a]

unstable families. However, no significant differences were found among the individual predisposing factors (conduct problems and pubertal development). Results also show that in poor neighborhoods, adolescents were more likely to affiliate with deviant peers. Finally, as expected, the age distribution for transitions to first sexual activity was significantly different in poor and more affluent neighborhoods, with significantly higher rates of transitions at 12 and 13 years old in poor neighborhoods.

Discrete-Time Hazard Models

To estimate the association between the risk factors and the timing of first sexual activity, discrete-time hazard models were used (Singer & Willett, 2003). This strategy is appropriate because the timing of first sexual activity was measured in terms of years, a discrete-time scale. Regular logistic regression routines can be used to estimate this type of model. In this case, the SAS LOGISTIC procedure estimated the regression coefficients separately in each of the five imputed data sets. Then, the MIANALYSE procedure recombined the results to obtain a final, single set of parameter estimates (Allison, 2001). Also, interactions between all risk factors and linear time were included. To test for these interactions, time was coded as a continuous variable ranging from 0 = *12 years old* to 3 = *15 years old*.

Bivariate Results

Table 2 shows results from bivariate discrete-time hazard models performed for adolescent females and males. For each gender, the first column presents the estimated odds ratio (OR) at 12 years old. For instance, the estimated OR associated with low family SES is 2.55 at 12 years old for adolescent females. This means that the odds of transitioning to sexual activity at 12 years old are about 2.5 times higher for adolescent females from low-SES families (i.e., with an SES score at least 1 *SD* below the national mean), compared with adolescent females from higher SES families. The second column contains the interaction effects with time, that is, the attenuating effect of every passing year. Continuing with the SES example, the first result in the second column for adolescent females indicates that the value of the OR associated with low SES diminishes by 24% ($1.00 - 0.76 = 0.24$) with every passing year. At 13 years old, the estimated OR becomes 1.94 ($2.55 \times 0.76 = 1.94$) and, finally, at 15 years old, it is 1.12 ($2.55 \times 0.76^3 = 1.12$). Thus, the effect of low family SES is strong in the early years of adolescence, but gradually fades away as adolescent females grow older, becoming negligible at 15 years old.

For adolescent females, the bivariate results show a significant effects for all the variables, except early pubertal development (although when the interaction

effect with time was excluded, the OR for this variable approached significance; OR = 1.09, 95% CI = 0.99–1.21). The ORs are especially large for affiliation to deviant peers and involvement with older partners. Low family SES, nonintact family status, and family residential instability, along with conduct problems and neighborhood poverty, were associated with higher risks of early sexual activity. Results also show that the effects of these risk factors were stronger in early adolescence and gradually faded as adolescent females grew older. The absence of significant effect for pubertal development is consistent with other NLSCY studies reporting no direct association between pubertal development measured at 10–11 years old and early sexual activity or other problem behavior in early adolescence among girls (Pepler & Sedighdeilami, 1998; Shapka, Dahinten, & Arım, 2006), although evidence suggests that when measured at later ages, this variable has a significant impact on the likelihood of being sexually experienced for both males and females (Garriguet, 2005). Thus, this result ought to be interpreted while keeping in mind the restrained variance of this variable at 10–11 years old (see Dorn, Susman, & Ponirakis, 2003; Udry & Billy, 1987, for a discussion of how the timing of measurement influence the estimated impact of pubertal development on adolescent behavior).

For adolescent males, the effects of the risks factors were generally smaller than for females, especially for peer characteristics. As opposed to females, family and individual predispositions were more important determinants of adolescent males' sexual behavior than peer processes. In this regard, the results are consistent with previous results showing that peers are more influential with respect to adolescent females' sexual behavior (Billy & Udry, 1985). Also, the effect of the risk factors tended to be more evenly distributed across time. For adolescent males, only one significant interaction effect with time was found (conduct problems) along with one marginally significant interaction effect (residential instability).

Bivariate models including interaction effects with gender were also examined for the combined sample to determine whether the differences between adolescent males' and females' coefficients were statistically significant (results not shown). Significant or marginally significant interaction effects were found for SES (B = .50, SE = 0.28; p = .087), pubertal development (B = .41, SE = 0.20; p = .041), neighborhood poverty (B = −1.54, SE = 0.71; p = .055), and peer deviance (B = −1.84, SE = 0.60; p = .006).

Multivariate Results

Three multivariate models were estimated for adolescent males and females. They gradually incorporate the predictors, starting with the most distal ones. The first model includes late childhood individual and family control variables, along with neighborhood poverty. In the second model, interaction terms between neighborhood disadvantage and predisposing individual and family risk factors are added. Only the interaction terms that were significant in preliminary analyses are included. In a final step, the more proximal peer processes were incorporated. This last step allows us to examine the potential mediating effect of peer processes. In all three models, interactions with time are included when appropriate.

Adolescent females. Table 3 presents the multivariate results for adolescent females. Model 1 shows that those living in poor neighborhoods were more likely to transition early, even after accounting for individual and family predisposing factors. The ORs were especially high in early adolescence and gradually faded as adolescent females grew older. For instance, at 12 years old, the odds of transitioning to first sexual activity were about 2.5 times higher in poor neighborhoods, but at 15 years old, the estimated ORs decreased to 0.74 ($2.46 \times 0.67^3 = 0.74$).

Model 2 reveals a significant interaction effect between neighborhood poverty and conduct problems and a marginally significant effect with residential instability. Because the OR associated with neighborhood poverty is no longer significant, adolescent females living in poor neighborhoods were more vulnerable *only* if they had a history of conduct problems and marginally so if they came from a residentially unstable family. To facilitate the interpretation of these interaction effects, Figure 1 presents the predicted probabilities of transition to first sexual activity as a function of age for various configurations of risk factors. The figure shows that among adolescent females residing in poor neighborhoods, only those with a history of conduct problems were more likely to transition early. The figure also confirms that the largest effects are found in early adolescence and gradually decline as adolescent females grow older. For instance, among adolescent females with conduct problems, the predicted hazard of transitioning to first intercourse, while holding other variables at their average values, is about 7.1 times higher in disadvantaged neighborhoods at 12 years old but only 1.2 times at 15 years old.

Finally, the last model in Table 3 shows that when the peer processes are included in the equation, the size of the interaction effects previously discussed is significantly reduced (e.g., the ORs are reduced by about 40% ($[6.69-3.78]/6.69$) for the interaction between neighborhood disadvantage and conduct problems) and the interaction terms become nonsignificant, thus indicating that peer characteristics partially accounted for the interaction effects found between individual and neighborhood risks. Also consistent with the proposed peer mediation model, Figure 2 illustrates that the peer risk factors are much

more prevalent for adolescent females with a history of conduct problems *and* who live in poor neighborhoods. For adolescent females in general, living in a poor neighborhood had little impact on peer characteristics.

Adolescent males. Table 4 presents the multivariate results for adolescent males. Consistent with the bivariate results, Model 1 shows that after controlling for preexisting family and individual risks, neighborhood disadvantage is not, on average, associated with accelerated transitions to first sexual activity. In contrast, nonintact family status, previous conduct problems, and early pubertal development all had independent, accelerating effects. Only one significant interaction effect with time emerged. This showed that the effect of previous conduct problems is stronger in younger adolescent males and attenuates as adolescent males grow older. Indeed, for those with a history of conduct problems, the estimated odds were 4.1 times higher at 12 years old but only 1.1 times higher at 15 years old ($4.1 \times 0.64^3 = 1.1$).

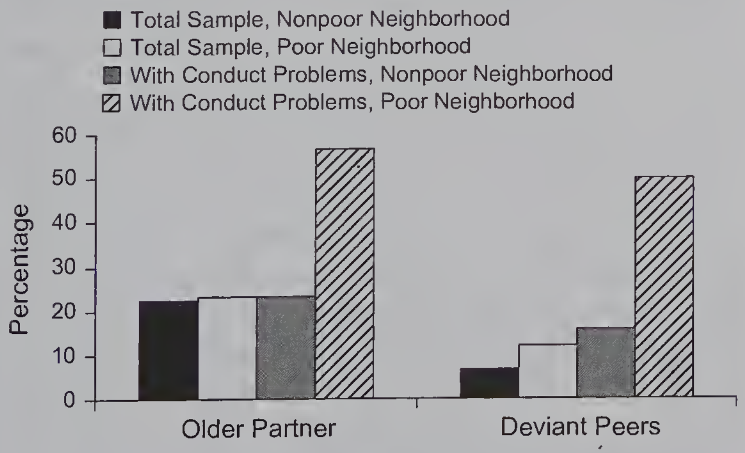

Figure 2. Adolescent females' peer characteristics as a function of neighborhood poverty status: Reported proportion of older partners (among those who transitioned to first sexual activity at 12 or 13 years old) and of deviant peers (at 12–13 years old) for adolescent females' total sample and among those with a history of conduct problems.

In Model 2, significant interaction effects between late childhood risk factors and neighborhood poverty emerged for conduct problems and family SES. Figure 3 unpacks these effects. It plots adolescent males' estimated probabilities of transition to first sexual activity as a function of age for different configurations of risk factors. Figure 3 shows that the differences are smaller compared with the results for females (Figure 2). In Figure 3, the only curve that is clearly distinguishable from the others is the one representing the probabilities of transition for adolescent males living in a poor neighborhood and who had histories of conduct problems and who were from low-SES families. As shown in the figure, the predicted probability of transitioning to first intercourse, while holding other variables at their average values, is about 3 times higher in disadvantaged neighborhoods at 12 years old and 1.8 times higher at 13 years old for adolescent males who combined risks at the neighborhood, family, and individual levels.

Model 3 examines whether these effects are attributable to the peer processes considered in this study. Results show that when the other variables are controlled, deviant peer affiliation and having an older partner are only marginally associated with early sexual activity and that these variables do not mediate the interaction effects discussed above. Indeed, the interaction effects remain significant or marginally significant and their magnitude is not significantly altered. In this final model for adolescent males, apart from the interaction effects discussed above, only the parameters associated with family structure and pubertal development remain significant.

Discussion

The goal of this study was to evaluate, within a developmental ecological framework, the link between the neighborhood poverty and the timing of first sexual activity in a sample of young adolescents. Results showed that ecological risk, namely, neighborhood disadvantage, was associated with early sexual initiation, but only for a subgroup of vulnerable adolescents. In contrast, the majority of young adolescents living in disadvantaged neighborhoods were not more likely to transition early. Importantly, neighborhood effects depended upon adolescents' developmental stage, gender, and background characteristics. Thus, the moderation hypotheses were generally supported. Consistent with the proposed peer mediation model, results also suggested that peer characteristics partly explained the increased risk for vulnerable young adolescents living in disadvantaged neighborhoods. In short, the confluence of developmental and ecological vulnerability was found to increase the risk of engaging in early sexual activity and peer characteristics appeared to partly explain this risk.

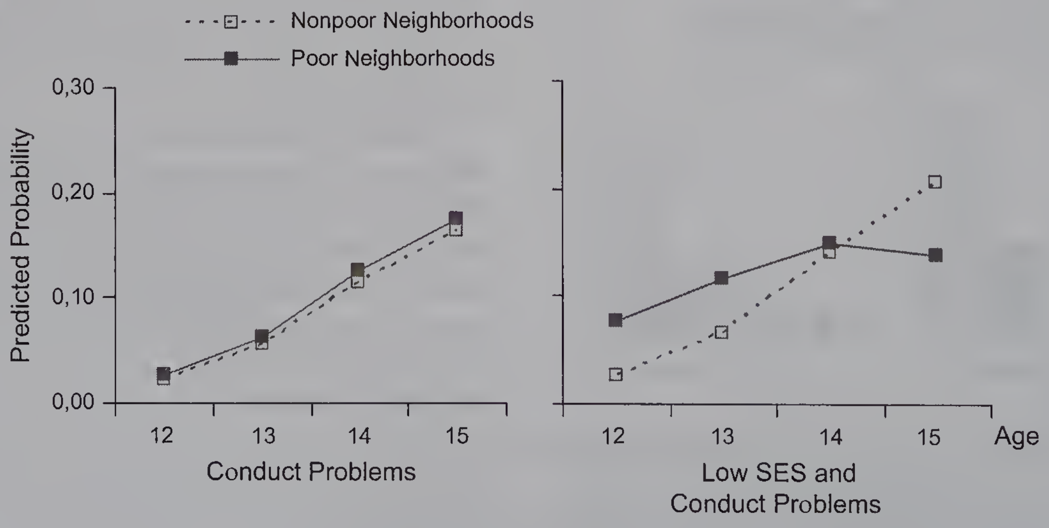

Figure 3. Adolescent males' predicted probabilities of transition to first sexual activity among those with conduct problems and among those with conduct problems and coming from a low-socioeconomic-status (SES) family, in poor and nonpoor neighborhoods, as a function of age.

For adolescent females, living in a poor neighborhood was associated with early initiation, but only for those who had a history of conduct problems. This effect was particularly strong in early adolescence, a time when sexual initiation is off-norm, and gradually faded as adolescent females progressed toward midadolescence, when it becomes more normative. Results suggested that adolescent females with conduct problems were especially at risk if they lived in poor neighborhoods possibly because in these contexts, they were more likely to affiliate with deviant, older males. In contrast, adolescent males living in poor neighborhoods were not, on average, more likely to experience early sexual initiation. However, results showed that if they had a history of conduct problems and were from a low-SES family, younger adolescent males living in poor neighborhoods were more vulnerable, as compared with adolescent males in more affluent neighborhoods with a similar profile. Among males, peer characteristics did not account for these interaction effects. Other mechanisms need to be considered in future research, such as the quality of neighborhood institutional resources or of parent–child relationships (Leventhal & Brooks-Gunn, 2000).

Consistent with Whitbeck et al.'s (1999) developmental model, many risk factors, including neighborhood disadvantage, had a stronger accelerating effect in early adolescence as compared with middle adolescence. The moderating impact of age is possibly due to the changing meaning of sexual activity across different developmental stages. Risk factors representing a departure from the norm, such as affiliation with deviant peers, predicted sexual initiation in younger adolescents, when this transition is clearly off-norms, but less so in older adolescents, when the transition becomes more normative. Interestingly, the moderating impact of age was generally stronger and more consistent among adolescent females than males, possibly because early sexual initiation represents a greater breach of social norms for them (Benda & DiBlasio, 1994). In addition to the changing meaning of sexual initiation as a function of age, other developmental processes might explain younger adolescents' increased sensitivity to neighborhood effects. For instance, as compared with older peers, younger adolescents are thought to be more susceptible to peer pressure and perceived social norms (Brooks-Gunn & Furstenberg, 1989).

In this study, neighborhood disadvantage had a direct, independent accelerating effect in adolescent females but not in males. This result is not wholly consistent with previous findings in the neighborhood literature. A study conducted with a sample of Black adolescents found an independent effect of neighborhood disadvantage only in males (Ramirez-Valles et al., 2002). Another study conducted in a racially diverse sample found comparable neighborhood effects in both genders (Browning et al., 2005). In contrast, the present study, using a virtually all-White sample, found significant direct neighborhood effects only in adolescent females. Gender differences in neighborhood effects appear to depend on adolescents' racial and cultural background perhaps because gender-specific norms regarding the optimal timing for entry into sexual activity vary considerably across groups (East, 1998). Because cultural norms prohibiting early sexual activity tend to be especially emphasized for White adolescent females, early sexual activity represents a greater breach of norms for them compared with other racial groups (Cavanagh, 2004). This could explain why, in this sample, peer group characteristics marking an evident departure from the norm, such as peer deviance, were strongly associated with early sexual activity for adolescent females but not for males. This interpretation is also supported by previous studies showing that peer norms are powerfully associated with White adolescent females' sexual behavior, an association that appears specific to adolescent females from this racial group (Billy & Udry, 1985). Clearly, additional research is needed to uncover the mechanisms underlying gender differences in neighborhood effects within different racial and ethnic groups.

Among adolescent females, the impact of preexisting conduct problems was exacerbated in disadvantaged neighborhoods, apparently because these adolescent females were more at risk for affiliating with older, deviant males if they lived in a poor neighborhood. At least two explanations might account for this effect. First, adolescent females with such a background might seek the company of peers with a similar behavioral profile. In disadvantaged neighborhoods, this selection process is potentially facilitated given the higher prevalence of problem behaviors (Sampson et al., 2002). By seeking the company of similar peers, these adolescent females might often affiliate with older, deviant males because as a group, older adolescent males exhibit the highest level of delinquent behaviors (Hirschi & Gottfredson, 1983). Reciprocation could reinforce this process, with older deviant males likely to find younger adolescent females attractive (Caspi et al., 1993). In this social context, peer norms concerning the desirability of sexual activity, as well as developmental imbalances, are potentially responsible for the increased likelihood of sexual initiation. Second, family processes might also play an important role. For instance, adolescents with conduct problems are especially impervious to parents' supervision efforts and inconsistent supervision is more strongly associated with early sexual initiation in disadvantaged neighborhoods (Browning et al., 2005). Thus, friendship preferences and family dynamics, in combination with an increased accessibility of deviant peers, might explain why in disadvantaged neighborhoods young adolescent females with a history of conduct problems are especially likely to engage in early sexual activity.

Finally, neighborhood poverty also amplified the effect of family disadvantage on early initiation. Adolescent males with a history of conduct problems and coming from a low-SES family were more likely to become sexually initiated in early adolescence, but only if they also lived in a poor neighborhood, and among adolescent females, those living in a poor neighborhood and originating from a residentially unstable family were marginally more at risk. Different mechanisms, in addition to the supervision pathway discussed above, may explain why the negative impact of family disadvantage appears reinforced in poor neighborhoods. First, adolescents from a disadvantaged family background may be more likely to develop a sense of hopelessness when their families' difficulties are echoed in their larger environment (Wilson, 1987). In turn, "nothing to lose" attitudes are associated with adolescent involvement in risk behaviors (Harris, Duncan, & Boisjoly, 2002). Also, residential instability may further reduce access to the already scarce social and institutional resources in disadvantaged neighborhoods. Notably, residential instability has a negative impact on the quality of adolescents' friendship networks. Indeed, adolescents who have recently moved to a new neighborhood have been found to be more likely to affiliate with deviant friends, which in turn increases the risk for early sexual activity (South et al., 2005).

The conclusions of this study should be considered with some important limitations in mind. First, even if special care has been devoted to circumvent possible bias due to attrition, limits to generalizability may remain. In particular, as noted above, the results might apply only to the cultural group studied. Second, even if important family and individual confounding factors were taken into account, the possibility of selection bias can never be fully ruled out. Indeed, there is always a chance that an omitted variable associated with both neighborhood poverty and sexual initiation is responsible for neighborhood effects. Third, as is often the case in large-scale studies investigating many aspects of development, some of the concepts investigated would have benefited from more thorough measurement strategies. For instance, in addition to retrospective information about the age of first sexual partners, prospective information about the age of boyfriends and girlfriends would have strengthened our results and refined our interpretations. In the same vein, additional details about the circumstances of first intercourse, such as the degree of consent, would have allowed us to make additional distinctions. Fourth, the survey questions did not allow distinctions between sexual initiations with same- and other-gender partners. For this reason, the explanatory model proposed, which is centered on other-gender sexual activity, misrepresents the experiences of adolescents engaging in same-gender sexual activities. In addition, even if the sample in this study is large, the main conclusions are based on relatively small numbers of individuals. Indeed, because the NLSCY is a normative sample, early intercourse was relatively rare. Replications of findings in other studies oversampling at-risk adolescents are warranted. Also, although results from prediction models are robust, point estimates of the proportion of sexually experienced adolescents at different ages can vary appreciably depending on how missing data and data inconsistencies are treated and for this reason should be viewed with caution (Upchurch, Lillard, Aneshensel, & Fang Li, 2002). Finally, because adolescent males are more likely than adolescent females to provide inconsistent reports of age at sexual initiation (Upchurch et al., 2002), some of the differing results observed for adolescent males and adolescent females might reflect this tendency. Notably, it might contribute to the lack of significant predictors of adolescent males' sexual behavior.

Another important limitation of the study is the uncertainty regarding the temporal order of the peer explanatory variables. It was suggested that adolescent females with conduct problems were more likely to affiliate with older, deviant males during early adolescence and that this tendency in turn placed them at risk for early sexual activity. However, because the peer processes were measured concurrently, it is equally possible that adolescent females were introduced into deviant peer groups through early sexual debut. Thus, because of the correlational nature of this study and because of the uncertain temporal order of the explanatory processes, causation cannot be directly inferred. More detailed interview data would be necessary to grasp the temporal ordering of the events leading to early sexual activity in various contexts.

This study used a developmentally oriented framework for examining the link between the neighborhood disadvantage and the timing of sexual initiation. In line with previous studies showing that the association between neighborhood disadvantage and early sexual activity depends on family characteristics

(Browning et al., 2005), this study further demonstrated that this association also depends on individual characteristics such as age and behavioral traits. By identifying young adolescents who are particularly at risk within disadvantaged communities, this study provides valuable insights for future intervention efforts. The results suggest that to maximize effectiveness, prevention programs need to take the larger social context into account and make special efforts to enroll vulnerable young adolescents. Also, the results suggest that additional research is needed that examine the role of neighborhood peers, a potentially important explanatory factor for neighborhood effects on adolescent sexual behavior. If future research confirms a causal role, prevention programs aimed at delaying first sexual activity could benefit from integrating strategies for reducing affiliation with deviant neighborhood peers.

Searching and Planning: Young Children's Reasoning About Past and Future Event Sequences

Kerry L. McColgan and Teresa McCormack
Queen's University Belfast

Six experiments examined children's ability to make inferences using temporal order information. Children completed versions of a task involving a toy zoo; one version required reasoning about past events (search task) and the other required reasoning about future events (planning task). Children younger than 5 years failed both the search and the planning tasks, whereas 5-year-olds passed both (Experiments 1 and 2). However, when the number of events in the sequence was reduced (Experiment 3), 4-year-olds were successful on the search task but not the planning task. Planning difficulties persisted even when relevant cues were provided (Experiments 4 and 5). Experiment 6 showed that improved performance on the search task found in Experiment 3 was not due to the removal of response ambiguity.

The development of flexible and imaginative thinking about nonpresent events has been the subject of recent attention. This cognitive ability has been described in many ways: for example, as episodic past and future thinking (Atance & O'Neill, 2001a), temporal decentering (Zelazo & Somerville, 2001), or temporal perspective taking (McCormack & Hoerl, 1999), but most notably as mental time travel (MTT; Suddendorf & Busby, 2003). Although there are differences between these descriptions, all these theorists emphasize the fact that there is a flexible type of thinking about events in the past and the future that is firmly established relatively late in development (around the age of 4–5). Despite the recent interest in the development of MTT, it remains the case that there have been relatively few attempts to characterize important, and perhaps associated, changes in the nature of temporal concepts and reasoning in the early years (for notable exceptions, see Nelson, 1996; Friedman, 2003; Weist, 1989).

According to our everyday conception of time, time is populated by a series of chronologically ordered events stretching from the present in two directions, into the past and into the future. Povinelli (2001; Povinelli, Landry, Theall, Clark, & Castille, 1999) has argued that mature temporal cognition requires not only the ability to chronologically order events in time but also an appreciation of the causal flow of events. Our everyday thinking about events in time is based on the awareness that chronological order is a result of "an inherent causal arrow of time that binds each state of the world to each succeeding one" (Povinelli et al., 1999, p. 1427). The temporal order in which events happen often affects the overall outcome of a sequence of events, due to the unidirectional nature of the causal arrow of time (earlier events will have an influence on later ones but not vice versa) and the causal relations between these events (later events in a sequence may change or remove the effects of events that occurred earlier in the sequence).

Flexible and insightful temporal cognition involves grasping the actual practical significance of this chronological organization, a significance that derives from its causal structure. This type of reasoning has sometimes been referred to as temporal–causal reasoning (McCormack & Hoerl, 2005; see also Welch-Ross, 2001). It is clear that from an early age, children are able to represent and remember temporal order information: For example, children younger than 2 years can reproduce novel action sequences in the correct order (Bauer & Mandler, 1989), and by 3 or 4 years, they can correctly order representations of sequences of familiar events, such as the main events of a typical day or a visit to the supermarket (Benson, 1997; Fivush & Mandler, 1985; Friedman, 1977). However, the extent to which preschool children can incorporate information about temporal order into their reasoning is less clear. Povinelli et al.'s (1999) argument is that the ability to represent and

remember such order information may be developmentally more primitive than the ability to use it to support inferences that require a consideration of event order. For example, can young children use information about the order in which a sequence of novel events have happened to make inferences about how the world must be now?

We have described this type of reasoning in question as temporal–causal reasoning, with the term *causal* used because such reasoning involves a consideration of the outcome or consequences of the order in which events have occurred or will occur. However, most of the developmental research that has been conducted on causal reasoning has focused on what might be termed causal powers reasoning, for example, whether a block has the causal power to make a machine light up and play a tune (Gopnik, Sobel, Schulz, & Glymour, 2001; for a review, see Corrigan & Denton, 1996). Temporal–causal reasoning may build on existing knowledge about causal powers, but temporal–causal reasoning tasks place an additional demand on children's inferential abilities over and above causal powers reasoning. Specifically, children need to not only consider the causal powers of events but also reason about the role played by event order in determining outcome.

Povinelli et al. (1999) and McCormack and Hoerl (2007) have examined this type of reasoning using simple object location tasks. In both their studies, an object was placed out of sight of the child, first in one location and then in another. At test, children were unexpectedly asked to locate the object but could only do so correctly by retrospectively considering the order of the two hiding events they had not previously observed. Children aged 5 years or younger had consistent difficulties with doing so. McCormack and Hoerl (2005) also examined preschool children's ability to reason about the causal significance of the order in which two events occurred. In their study, children were required to judge which of two objects could be found in the window of a novel mechanical box. Answering correctly required a retrospective consideration of the order in which two button presses involving the box had occurred. Again, children younger than 5 years performed at chance levels on this task. These recent studies suggest that basic temporal–causal reasoning abilities are still developing between 4 and 5 years and provide support for Povinelli et al.'s suggestion that children can represent order information before being able to exploit it in their reasoning. However, this research has focused solely on reasoning involving short sequences of events that occurred in the past and has not examined reasoning involving event sequences located in the future.

In the experiments reported, we designed tasks to measure temporal–causal reasoning about event sequences for both the past and the future. The tasks involved mentally revisiting past events or imagining future events and considering the causal consequences of the order in which such events had occurred (past version of the task) or were to occur (future version). As described and explained below, a search task was used as a measure of temporal–causal reasoning concerning the past and a simple planning task as a measure of reasoning concerning the future. Based on a suggestion by Goswami (1998), both versions involved a visit of a doll to a toy zoo that carried a camera.

Reasoning About Past Event Sequences

Although relatively few studies have explicitly examined the development of temporal–causal reasoning, some previously established tasks in the literature can be easily interpreted as placing demands on this type of reasoning even though they have been used to investigate other cognitive abilities. For example, in some previous studies of children's search behavior, searching has taken place after children have visited a series of locations (e.g., Anooshian, Hartman, & Scharf, 1982; Haake, Somerville, & Wellman, 1980; Wellman, Somerville, & Haake, 1979). Participants' visits to each location and the activities carried out at locations can be viewed as a sequence of events that has unfolded over time. Typically, the tasks have involved locating an object that has previously been used during an activity at a certain point in the sequence, with children being unaware in advance that they would be required to locate the object. Children were thus required to think retrospectively about the order in which events in the sequence had occurred and use such a consideration to infer a state of the world—specifically, the possible location of the object. Clearly, such search tasks load on a variety of cognitive abilities, in particular memory and spatial abilities. However, some of these tasks also require temporal–causal reasoning, in that accurate performance depends on a consideration of the causal significance of the order in which events have occurred. For example, Wellman et al.'s (1979) task involved children who, after visiting a series of locations, had to search for a missing camera that had been used at a specific location in the sequence. Although the youngest children were often able to correctly return to the location where the picture had been taken, only the older children were consistently able to infer the only other logically possible locations of the object. This suggests that younger children may just have looked in the place the camera had last been used based on its association with that location. Although other studies have attempted to rule out such an associative explanation (Anooshian et al., 1982; Haake et al., 1980), their findings do not straightforwardly permit the conclusion that young children realize that only certain locations are logically possible, given the sequence of events that has unfolded.

Our task resembled such tasks in that it involved a single trial, thus eliminating the possibility of perseveration at certain search locations across trials (see Suddendorf, 2003). Furthermore, as in these previous search tasks, children were unaware in advance that they would need to search for an object, ruling out the possibility that responses could be based on simple object tracking rather than retrospective reasoning, However, our search task differed from these previous tasks in a number of ways. First, a simple associative response (in the case of our task, choosing the location where the camera was last used) was not possible. Second, children were given only a single opportunity to choose a location so that responses could be easily interpreted and classified. Third, most previous search studies have been conducted in large-scale relatively complex spatial environments; in our task, the spatial layout was deliberately extremely simple. Last, given that Wellman et al. (1979) found that younger children were not always able to recall the last location in which an object (also a camera) was used, we provided children with a memory cue in the form of a Polaroid photograph that had been taken with the camera. Furthermore, the fact that temporal order was mirrored in the spatial layout available to the child at test meant that children did not have to conduct an extensive memory search to reconstruct the sequence of events, reducing the possibility of failure due to memory rather than reasoning problems. It was hoped that these various modifications would ensure that children who failed the task would do so because of poor temporal – causal reasoning abilities rather than because of deficits in other cognitive skills such as memory or spatial cognition.

Reasoning About Future Event Sequences

Children's ability to consider the order of event sequences in the future has previously been studied using a wide variety of planning tasks (Bauer, Schwade, Wewerka, & Delaney, 1999; Benson, 1997; Hudson & Fivush, 1991; Hudson, Sosa, & Shapiro, 1997; Wellman, Fabricius, & Sophian, 1985; see Scholnick, Friedman, & Wallner-Allen, 1997, for a review). Atance (Atance & O'Neill, 2001b) has developed planning tasks for use with young preschoolers, and her findings have suggested that at least some 3-year-olds can make simple plans. However, the tasks that she has used are typically one-step planning tasks that do not actually require a consideration of temporal order of a future sequence of events. In contrast, traditional formal planning tasks such as the Tower of London/Hanoi task require a consideration of the order in which actions in a sequence must be executed (Scholnick et al., 1997). Some studies have used versions of such traditional planning tasks to examine development (e.g., Klahr & Robinson, 1981; Welsh, 1991), although these tasks have not always proved straightforward to administer to younger children (Luciana & Nelson, 1998). In general, their findings suggest marked improvements between 3 and 5 years (e.g., Carlson, Moses, & Claxton, 2004; Welsh, 1991), in line with findings from planning tasks set in more naturalistic contexts (Hudson et al., 1997). The planning task used in the present experiments differed from many previous planning tasks (e.g., those employing the Tower of London/Hanoi) in that children were deliberately given only a single trial, without any initial demonstrations by the experimenter or the opportunity to improve their performance over a number of trials. Thus, performance could not be based on acquired strategies or routines. Furthermore, in contrast to some planning tasks (see Hudson et al., 1997), the event sequence was entirely novel so that children could not use their knowledge of either familiar event sequences or a sequence they had recently observed to answer correctly.

Comparing Past and Future Reasoning

A common feature of the theoretical accounts mentioned at the start of this article is that they are intended to encompass cognition about both the past and the future. For example, on Suddendorf's account, MTT to the past and MTT to the future are skills that would be expected to go hand in hand because they involve a common core cognitive ability (see also Atance & O'Neill, 2005). Despite this, there is little research that has directly compared whether the development of such skills emerges simultaneously. Neuropsychological research has begun to examine the extent to which reasoning about the past and imagining the future involve common brain areas (e.g., Hassabis, Kumaran, Vann, & Maguire, 2007; Szpunar, Watson, & McDermott, 2007). Moreover, recent comparative research has explored whether certain animal species are capable of both thought about the past and the future (e.g., Clayton, Bussey, & Dickinson, 2003; Raby, Alexis, Dickinson, & Clayton, 2007). However, relatively little research has attempted to directly compare the development of temporal cognition concerning the past with the development of that concerning the future, although this issue is beginning to attract attention (Busby & Suddendorf, 2005; Hudson, 2006).

Busby and Suddendorf (2005) attempted to address this issue by using a verbal task to elicit both past and future talk from young children. They found that 4- and 5-year-olds could answer questions about both the past and the future equally well and found no age-related differences. They take their findings as a demonstration that the ability to engage in MTT to the future and to the past emerge in tandem. In contrast, Hudson (2002, 2006) has argued that preschool children find it more difficult to engage in conversation about the future than about the past. Hudson has also argued that the ability to remember event sequences may precede the ability to use such memories to flexibly plan for the future (Hudson et al., 1997; see also Benson, 1997). Other related research conducted by Friedman (for a summary, see Friedman, 2003, 2005) has examined young children's abilities to judge the relative distance from the present of both past and future events. Looking across the findings of his studies, it would appear that the ability to make judgments of this sort for future events appears to develop somewhat later than for past events. Indeed Friedman (2005) has argued that, at least in young children, qualitatively different types of processes may underpin such judgments for the past and the future.

The series of experiments described below examined the development of temporal–causal reasoning for both past and future sequences of events, using our simple search and planning tasks. If these tasks measure a common ability, then we might expect to see similar developmental patterns for both the tasks. Experiments 1 and 2 examined how performance changed between 3 and 5 years on the two tasks. In Experiments 3–5, we examined whether performance could be improved by using a shorter sequence of events, and Experiment 6 explored possible explanations of the effect on performance of reducing the number of events in the sequence in the search task.

Experiment 1

Method

Participants

One hundred and eighty children took part in the task; 60 in each of the three age groups tested, with half in each age group taking part in the search task and half completing the planning task. The groups comprise sixty 3-year-olds (search: M = 44 months, range = 40–47 months; planning: M = 45 months, range = 41–47 months), sixty 4-year-olds (search: M = 55 months, range = 51–59 months; planning: M = 55 months, range = 49–59 months), and sixty 5-year-olds (search: M = 68 months, range = 60–71 months; planning: M = 68 months, range = 60–71 months). There were 85 boys and 95 girls. All children were of Caucasian descent and were mainly from working- and middle-class backgrounds. Participants were drawn from nurseries and schools local to the first author. For both versions of the task, children were tested individually in a quiet area away from the other children in the group or class. The tasks took approximately 10 min each, and all children received a set of stickers for taking part.

Materials

The same novel zoo apparatus was used for both tasks (see Figure 1a). This comprised a large rectangle of green felt on which was sewn a gray felt semicircular path. Five cages, with a different miniature plastic animal in each, were placed at regular intervals along the curve of the path. These animals were a giraffe, zebra, kangaroo, elephant, and a tiger. The cages were of different dimensions (between 17 × 11 cm and 23 × 16 cm) to accommodate the different sizes of the animals. Four boxes (referred to as lockers), each measuring 21 × 24 cm, were placed behind the cages of the animals at the first, second, fourth, and fifth locations visited along the path. These lockers were hinged at the top, which enabled them to be opened up. During the task, the lockers were placed in such a way that they opened away from the experimenter, ensuring that participants were unable to see into them. A Polaroid camera, measuring 18 × 5 cm, was used in both tasks, and a soft female toy doll (Molly) measuring 38 cm high was the actor in the two tasks. The procedure of the search task involved the doll's camera being "lost" at either Location 4 or 5 along the path. In order to achieve this without the child's knowledge, a second duplicate camera was used. This meant that one camera could be hidden in an appropriate locker from the outset of the task, whereas the other was carried by the doll during the task.

A green felt rucksack measuring 25 × 22 cm was designed to hold the camera that was used during the task, as well as additional items. The rucksack fitted onto the doll's back. Two identical versions of this were required. One of these bags (the original bag)

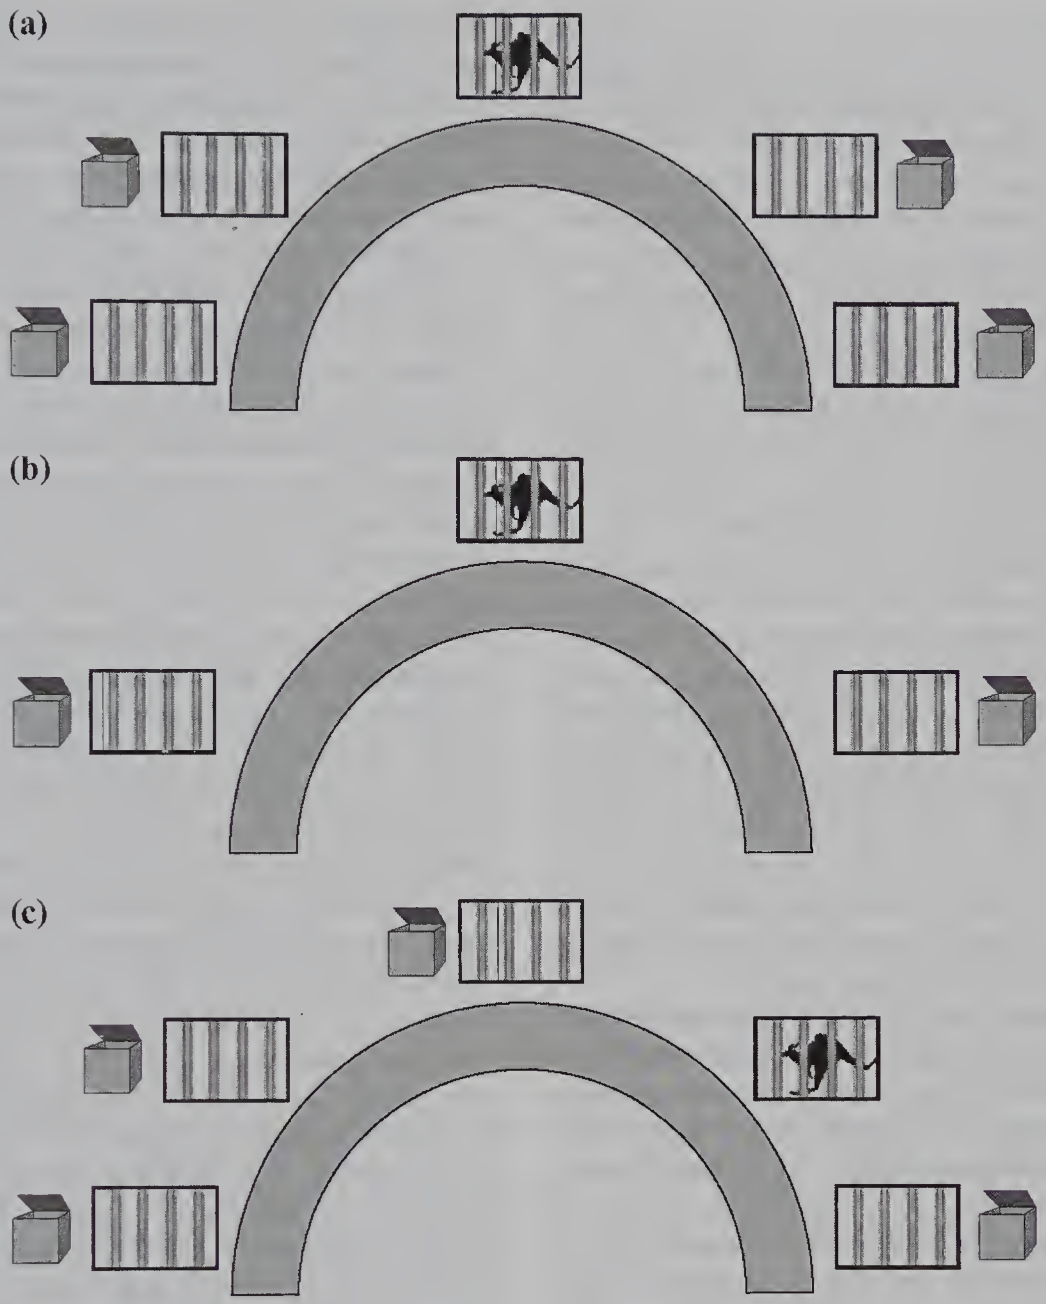

Figure 1. Schematic drawing of the layout used in (a) Experiments 1 and 2, (b) Experiments 3–5, and (c) Experiment 6.
Note. For ease of visualization of the array, boxes are shown in this figure positioned as if the child could see inside each of them when opened. However, in all studies, the boxes were rotated 180°, so that the child could not see inside any of them when opened by the experimenter.

contained all the items listed below and the camera. The other bag contained all the items listed below but no camera (the duplicate bag). The additional items were (one for each of the bags): a toy dog, a notebook, and a small bottle of juice. The rucksacks were constructed such that when closed, the contents of the bag could not be discerned; thus, it was impossible to tell whether or not the bag did or did not contain the camera simply from viewing its exterior. A doll's coat was used as part of the distracter task. The order in which the animals were placed along the zoo's path was varied in order to control for the possibility that a child's response may have been influenced by the location of their favorite animal. There was one restriction to these variations, which was that the kangaroo's cage was always placed at Location 3, which was the middle location in this study.

Procedure

At the beginning of the task, children were seated in front of the zoo, directly facing the middle cage, and equidistant from all the other locations.

Search task. Prior to the start of the task, before children were present, the second camera was placed by the experimenter in the box at either Location 4 or 5 along the path (this was counterbalanced). It remained there throughout the experiment, although children could not see it throughout the procedure. The duplicate bag was also hidden in a suitable place somewhere out of view of children, where it could be quickly retrieved by the experimenter. Additionally, in order to provide a brief distracter task, the doll's coat was positioned somewhere just outside the testing room, so that in order to retrieve it, children would have to leave the room. This gave the experimenter time to swap the original bag with the duplicate one.

When children were seated, they were introduced to Molly and told that she was at the zoo. They were given a brief description of the nature of the zoo. The experimenter told children that Molly had a bag with her and then showed them all the contents of the bag. In particular, children's attention was directed toward the Polaroid camera. They were told that this type of camera produced the photo "nearly right away." To demonstrate this, a photo was taken of Molly. To help children's understanding, the experimenter showed children the photo and explained to them that at the start, you couldn't see the picture of Molly, but after a while, the photo changed color and you could see Molly. Once children had seen the fully developed photo, they were shown the lockers beside the cages at Locations 1, 2, 4, and 5. The experimenter told children that these lockers could be opened up, and so whenever Molly visited an animal with a locker beside it, she should put her bag into it.

At this point, the experimenter explained to children that there was a path in the zoo that the doll had to go round, which the experimenter traced with their finger, going from children's right to left. They were told that Molly had to go a certain way around the zoo and that she could only go round it once and so could not go back again and revisit an animal. In order to determine if children understood these instructions, the experimenter asked them to point to the start and end of the path and to show her which way round the zoo the doll had to go. Once these details had been explained to children, the experimenter took the doll to Location 1. The bag was taken off the doll and put into the locker that was beside this cage. Children and the experimenter then talked about the animal for a short while and then the experimenter retrieved the bag from the locker, put it back on the doll's back, and then moved on to Location 2 where this sequence was repeated.

At Location 3, however, the experimenter pointed out that there was no locker beside the cage there, and therefore this meant that the bag had to stay on Molly's back. It was suggested that because Molly had her bag with her, they should take a photo of the kangaroo, which was the animal in that cage. The camera was removed from the bag and a photo was taken that was then placed in front of the kangaroo's cage, where it stayed for the remainder of the task. The experimenter then put the camera back in the bag, with children being made aware that she was doing so. The experimenter then took the doll to Locations 4 and 5 in turn, and again, at each of these locations, the bag was taken off the doll's back and placed in the respective lockers, as with Locations 1 and 2.

When the doll reached the end of the zoo and had visited all the animals, participants were given a brief distracter task. This involved them being asked to retrieve the doll's coat which, as previously mentioned, had been placed just outside of the room. While children were away from the room, the experimenter exchanged the original bag that had been used during the task (with the camera) for the duplicate bag without the camera. When children returned, the experimenter told them that the camera was missing and let them look in the bag to see for themselves. She told children that the camera must have fallen out whenever the bag was being put into one of the lockers. Children were then shown the photo of the kangaroo that had been taken during the task and told "She had it earlier because she took this nice photo of the kangaroo. Shall we help Molly find her camera?" The experimenter then asked children what locker they thought the camera might be in. They were told that it was only possible to look in one location. Children's answer was taken as the locker that they pointed to. The correct answer for this task was either Location 4 or 5 (regardless of where the duplicate camera had actually been hidden). The experimenter looked in the locker that children had indicated: If the camera was in that location, she showed them that they had chosen correctly; if it was not, she showed them the true location of the camera. Regardless of whether or not children had found the camera, they were thanked for taking part and given a sticker of their choice.

Planning task. Once children had been seated, the experimenter introduced them to the doll, Molly. In this task, they were told that, "Molly will be going to the zoo." As in the search condition, children were given a brief description of what a zoo was. The experimenter then told children, "Molly has a camera with her that she wants to bring to the zoo." The Polaroid camera was shown to them, and the experimenter explained how it worked; as in the search task, this was demonstrated by taking a photo of Molly. Children were then told that Molly did not have a bag with her and so that she could not carry the camera round the zoo. It was pointed out to them that there were lockers beside some of the cages in the zoo (at Locations 1, 2, 4, and 5 along the path), and that these lockers could be opened up and objects placed inside them. It was suggested, "You could leave the camera in one of these lockers and then Molly could get it when she's going to the zoo."

As with the search task, the experimenter then showed children that there was a path in the zoo that the doll must follow, with the experimenter tracing the path (from the child's right to left) with her finger. They were told that Molly must follow the path whenever she went to the zoo and she could only go round the zoo once and could not revisit locations. Children were asked to point to the start and end of the path to show that they had understood the experimenter. Children were then told, "Molly wants to take a picture of the kangaroo when she goes to the zoo." They were asked to point to the location of the kangaroo in the zoo, with all children giving the correct answer. The experimenter pointed out that there was no locker beside the kangaroo's cage, and so there was no place to leave the camera. It was proposed that, "You could leave the camera in one of the other lockers and then Molly could get it when she goes round the zoo. What locker could you leave it in so that Molly is still able to take a photo of the kangaroo?" If they did not answer, the experimenter prompted them. However, no location was suggested to children. As in the search task, children's answer was taken as the location of the locker that they pointed to.

Results

In both tasks, there were four locations that the child could possibly choose (Location 3, the kangaroo's cage, was not a legitimate response as there was no locker beside this cage). For each task, two of these were correct; in the search task, these were Locations 4 and 5, and in the planning task, these were Locations 1 and 2. Table 1 summarizes children's performance. Two-tailed binomial tests revealed that on the search task, neither 3-year-olds nor 4-year-olds performed at a level above chance ($p > .05$ for both year groups). Five-year-olds, however, performed significantly above chance on this task ($p < .01$). Further analyses were carried out to determine whether there were any differences in performance among the age groups. These showed that although there was no significant difference in performance between the 3- and 4-year-olds, 5-year-olds performed significantly better than both these groups, $\chi^2(1) = 11.59, p < .01$, and $\chi^2(1) = 10.00, p < .01$, respectively.

As in the search task, neither 3- nor 4-year-olds performed at a level exceeding chance in the planning task ($p > .05$ for both year groups), but a greater proportion of 5-year-olds passed this task than would have been expected by chance ($p < .05$). Unlike the search task, however, there were no significant differences in performance between any of the age groups. Indeed, as can been seen in Table 1, the number of 5-year-olds passing this task is very similar to the number of 4-year-olds, although only the 5-year-olds performed significantly above chance as a group. For each age group, further analyses examined whether performance was significantly better on one of the tasks. For both the 3-year-olds and the 5-year-olds, there was no difference in children's performance on the two tasks. However, significantly more 4-year-olds passed the planning task than the search task, $\chi^2(1) = 4.29, p < .05$.

Table 1

Number of Children in Each Age Group Who Passed or Failed as a Function of Age Group and Task

	Age group	Task	Pass	Fail
Experiment 1	3-year-olds	Search	11	19
		Planning	16	14
	4-year-olds	Search	12	18
		Planning	20	10
	5-year-olds	Search	24	6
		Planning	21	9
Experiment 2	4-year-olds	Search	16	14
		Planning	19	11
	5-year-olds	Search	24	6
		Planning	23	7
Experiment 3	4-year-olds	Search	23	7
		Planning	16	14
Experiment 4	4-year-olds	Search	24	6
		Planning	18	12
Experiment 5	4-year-olds	Planning	17	13
Experiment 6	4-year-olds	Search	15	15

Note. $n = 30$ for each age group in each task.

Additional analyses of children's choices of location were also conducted. Children's location responses were divided into correct and incorrect answers, and for each of these categories of responses, two-tailed binomial tests were carried out to examine whether one location was chosen significantly more frequently than the other. Table 2 shows the location choices for each age group; correct choices for each task are in bold. In the search task, a significant majority of both 3- and 4-year-olds chose Location 1 over Location 2 whenever they gave an incorrect answer ($p < .05$ for both age groups). However, there was no tendency for 5-year-olds to favor either of these two locations. Whenever children gave a correct answer, there was no significant difference between the frequency with which Locations 4 and 5 were picked.

In the planning task, both the 3- and the 5-year-olds chose Location 4 significantly more often than Location 5 whenever they answered incorrectly ($p < .05$).

Table 2
Distribution of Responses Across Locations as a Function of Age Group and Task

			Location			
	Age group	Task	1	2	4	5
Experiment 1	3-year-olds	Search	15	4	**4**	**7**
		Planning	**5**	**11**	13	1
	4-year-olds	Search	14	4	**4**	**8**
		Planning	**3**	**17**	7	3
	5-year-olds	Search	2	4	**11**	**13**
		Planning	**3**	**18**	8	1
Experiment 2	4-year-olds	Search	4	10	**7**	**9**
		Planning	**0**	**19**	11	0
	5-year-olds	Search	3	3	**11**	**13**
		Planning	**6**	**17**	6	1
Experiment 6	4-year-olds	Search	5	3	7[a]	**15**

Note. $n = 30$ for each age group in each task. Correct responses are given in bold.
[a] Due to the layout of the lockers in Experiment 6, these are in fact choices of Location 3 rather than 4, see Figure 1c.

There was no difference in 4-year-olds' choice of location for incorrect answers. Whenever children responded correctly, 4- and 5-year-olds picked Location 2 significantly more frequently than Location 1 ($p < .05$). In this case, though, 3-year-olds did not choose one location significantly more often than the other.

Discussion

The results of this experiment suggest that by 5 years, children can reason about novel event series both in the past and in the future. However, children had difficulties reasoning about novel event sequences before the age of 5, and this was true for event sequences located in both the past and the future. These general findings are consistent with the previous research of Povinelli et al. (1999) and McCormack and Hoerl (2005, 2007), although the event sequences were longer in the current experiment than the two-event sequences used in those studies. However, although 4-year-olds did not perform at levels significantly above chance on either task, they performed significantly better on the planning task than on the search task, performing at a level on the planning task that was very close to that of the 5-year-olds (only one additional child passed in the 5-year-old group compared to the 4-year-old group). This preliminary finding might suggest that there is an asymmetry in children's ability to make temporal–causal inferences concerning past and future event sequences, with 4-year-old children more able when thinking about the future than the past.

Such a suggestion might be thought to run contrary to suggestions that temporal cognition develops in tandem for the past and future. However, it is important to rule out a potentially simple explanation of this initial task difference that is suggested by the analyses of children's choices of location, specifically 3- and 4-year-olds' errors on the search task. Children of this age chose Location 1 more often than Location 2 whenever they gave an incorrect answer. This suggests that some children may have been attempting to engage in a serial search strategy instead of attempting to search logically: In other words, children may have tended by default to start to search at Location 1 with the intention of then searching sequentially at Locations 2, 4, and 5. However, because children were given only a single opportunity to choose a search location, they would have been unable to complete such a serial search. This interpretation of error patterns is consistent with the previous findings of Wellman et al. (1979; Experiment 2), who have suggested that young children may adopt such an unreflective strategy when it is relatively effortless to search. Thus, it is possible that performance on the search task was poorer in 4-year-olds than on the planning task because performance on the search task in part reflects a default to use an unproductive serial search strategy. In the planning task, no such preference for the first location was observed.

Experiment 2

Experiment 2 was designed as a replication of Experiment 1, but there were a few important changes to the procedure. The most pertinent, given the patterns of location choices in the previous experiment, was that the method of responding was manipulated to discourage any tendency in young children to search serially. In Experiment 2, children were given a single sticker with which to indicate their response, instead of being allowed to point to their answer. By giving children only one sticker, it was hoped that children would realize that they could only choose one location. Furthermore, if it is assumed that pointing to the first location (to initiate a serial search) is a prepotent response, then previous research would suggest that introducing an alternative method of indicating an answer might ensure that children give a more considered response (e.g., Hala & Russell, 2001). Experiment 2 also addressed the possibility that 3- and 4-year-old children's failure on the tasks could have been due to a memory failure rather than a failure to reason correctly. In particular, there are two important pieces of information that must be remembered in order to make the appropriate temporal–causal inferences. These are (a) the direction the doll went round the zoo or was going to go round the zoo (indicating an awareness of the order in which events happened/are to happen) and (b) the location where the camera had been used or was going to be used (the causally significant piece of information that determines where the child should look for or place the camera). Therefore, in Experiment 2, two memory control questions were included to ascertain whether this information was remembered.

Method

Participants

One hundred and twenty children took part in the task. Sixty 4-year-olds were tested, 30 on the search task (M = 53 months, range = 48–58 months) and 30 on the planning task (M = 53 months, range = 48–58 months). Similarly, thirty 5-year-olds were tested on the search task (M = 68 months, range = 60–71 months) and 30 on the planning task (M = 67 months, range = 60–71 months). There were 59 boys and 61 girls. These children were recruited from nurseries and schools local to the first author. They were primarily from working- and middle-class background. One hundred and seventeen children were of Caucasian descent, 2 were of Black descent, and 1 was of Asian descent. None of the children had previously taken part in Experiment 1. Children were tested individually in a quiet part of their school, and each was given a set of stickers for participating. Only children who gave the correct answer to both the memory control questions were included in the sample. An additional five children were tested who were subsequently excluded from analysis due to failure to answer one or both these questions correctly.

Materials

These were identical to Experiment 1, with the addition of small circular stickers. In both tasks, one sticker was given to participants and they had to use this to indicate their response.

Procedure

Search task. This was identical to the procedure used in Experiment 1 up until the point at which children were asked the test question. After the test question, children were given a small circular sticker and asked to place the sticker on the locker where they thought the camera might be in. They were told that they had only one sticker so could only look in one location. Before the experimenter looked into the chosen locker to see if the camera was there, but after children had made their choices, two memory control questions were asked. Children were asked what direction the doll had gone round the zoo and also what animal the doll had taken a photo of.

Planning task. This followed the procedure of Experiment 1 up until the end of the familiarization with the zoo. Instead of proceeding to the test question, children were given a brief distracter task, identical to that used in the search task. This made the planning task more comparable to the search task in that there was a short period of time when children's attention was not directly focused on the task. When children returned, they were asked the same test question as in Experiment 1, but they were now given a sticker and asked to place it on the locker that they thought the camera should be left in. After children had placed the sticker on one of the lockers, they were then asked the appropriate version of the two memory control questions.

In addition to these procedural changes, the direction in which the doll traveled/was to travel round the zoo was counterbalanced in this version of the task; for half the children, it was clockwise and for half anticlockwise.

Results

Initial analyses confirmed that there was no effect of the direction of travel in the task (clockwise or anticlockwise). This finding is consistent with the previous findings in the search literature (Haake & Somerville, 1985). Two-tailed binomial tests showed that 4-year-olds failed both the search task ($p > .05$) and the planning task ($p > .05$). Five-year-olds again performed significantly above chance on both tasks ($p < .01$). There was a significant difference between the two age groups in the search task, $\chi^2(1) = 4.8, p < .05$, but no difference between these age groups in the planning task, $\chi^2(1) = 1.27, p > .05$. There was now no difference in 4-year-olds' performance on the two tasks, $\chi^2(1) = .62, p > .05$. Unlike in Experiment 1, this age group did not do better on the planning task than on the search task. There was again no significant task difference for the 5-year-olds, $\chi^2(1) = 0.10, p > .05$.

On the search task, 4-year-olds now showed no significant preference for either Location 1 or Location 2 when their answer was incorrect (see Table 2; $p > .05$). Five-year-olds also showed no significant preference for one of the two locations when their answer was incorrect. Whenever a correct answer was given in the search task, neither 4- nor 5-year-olds chose one of the two locations significantly more than the other. In the planning task, however, there were significant differences in children's choice of location both when they gave a right and a wrong answer. Four- and 5-year-olds were more likely to choose Location 2 over Location 1 whenever they gave a correct response ($p = < .001$ and $p < .05$, respectively). Whenever an incorrect answer was given, 4-year-olds more often chose Location 4 than Location 5 ($p < .001$); this difference was not significant for the 5-year-olds.

Discussion

These results supported the main finding of the first experiment, which was that 5-year-olds were successful on both tasks. However, children younger than 5 years again had difficulties with both the search and the planning tasks. Unlike in Experiment 1, 4-year-olds did not find the planning task significantly easier than the search task. The main reason for the disappearance of the task effect appears to be the experimental modification introduced in the second experiment—the use of a single sticker as a mode of response. In Experiment 2, 4-year-olds showed no preference for choosing the first location in the search task, suggesting that this modification successfully discouraged children from using a serial search strategy. Thus, the results seem to suggest that the task difference for 4-year-olds found in Experiment 1 may have been due to the adoption of a particular strategy that may have somewhat depressed performance on the search task rather than any fundamental difference between the ability to reason about the past and the future. What the overall results of Experiment 2 show, though, is that children's failure of the search task in Experiment 1 was not solely due to errors resulting from a serial search strategy, as 4-year-olds still did not pass this task even when the response mode was modified. This is despite the fact that all the children included in the analyses answered the memory control questions correctly. This means that it cannot be that children's incorrect answers to test questions are due to a failure to remember these important bits of information. It is clear that knowledge of these pieces of information is not enough for successful performance; rather, an additional important cognitive skill is needed, which requires integrating these pieces of information.

Before turning to the next experiment, one important issue that needs to be considered is whether 3- and 4-year-olds' difficulties on the tasks in Experiments 1 and 2 were due to the fact that the object in question was a camera and the relevant event involved taking a photograph. Such an interpretation of children's difficulties might be raised by Zaitchik's (1990) influential research that has suggested that young children have some difficulties in fully grasping the representational nature of photographs. One reason for doubting such an interpretation is that subsequent research has suggested that 3-year-olds can pass Zaitchik's false photograph task if their attention is focused on the photograph itself (Perner, Leekam, Myers, Davis, & Odgers, 1998; Slaughter, 1998; though see Sabbagh, Moses, & Shiverick, 2006). In any case, our search and planning tasks placed minimal demands on the understanding of photographs and certainly less than required to pass the false photograph task. In particular, children were not required to grasp that photographs may fail to match current reality. The future task simply required children to know that a certain object (i.e., the camera) will be needed at a certain point in time. To interpret the test question, children did not need to know anything about the nature of photographs over and above the bare fact that the activity to be carried out in the future—the taking of the photograph—would involve the camera. The pretraining session provided a demonstration of this function of the camera. The search task did place an additional demand on children's understanding of photographs, in that the photograph taken of the kangaroo present during test was intended to serve as a reminder to children of when the camera had been used. In order for the photograph to act effectively as a cue, children needed to grasp that it was taken using the camera when the doll visited the kangaroo. Such a grasp has two elements: (a) basic knowledge that the photograph was taken by the camera (an analogous demand to that of the future task) and (b) an awareness of the correspondence between the object depicted in the photograph and the real object. A considerable body of research suggests that by 3 years, children have no difficulties grasping such photograph – object correspondences (e.g., DeLoache & Burns, 1994; Liben, 2003; Suddendorf, 2003).

Experiment 3

The results of the first two experiments suggested that the children younger than 5 years have difficulties making inferences about past and future event sequences. However, 3- and 4-year-olds' difficulties on the search task might be thought to contrast with the success of much younger children on tasks that to some extent share its structure. In double invisible displacement tasks, children have to search for an object that has been invisibly displaced behind one of two occluders that have been sequentially visited, with correct search involving ignoring irrelevant distracter occluders. Recent studies of invisible displacement in children have been carried out in a comparative context (Barth & Call, 2006; Collier-Baker & Suddendorf, 2006); taken together, the general conclusion that can be drawn from these studies is that 2-year-olds can pass at least some double invisible displacement tasks. Two-year-olds' success on such tasks is in marked contrast with the difficulties of 3- and 4-year-olds on our search task in Experiments 1 and 2 and forces a consideration of why our task is harder.

There are important differences between our search task and double invisible displacement. In many versions of the latter task, the order in which locations were visited is irrelevant, and indeed children seem to choose randomly between first and second visited locations (Collier-Baker & Suddendorf, 2006). However, there is in fact a more complex version of the task which is structurally more similar to our search task and that does seem to require a consideration of event order. Somerville and Capuani-Shumaker (1984) used a multiple-trial object search task in which children had to search for an object that was initially hidden in the experimenter's hand that they then tracked as it moved sequentially behind a series of four screens. In one version of the task, after the hand had visited the second screen, children were shown whether or not it still contained the object. Unlike in most invisible displacement tasks, the hand then visited the remaining two screens, with search being postponed until all four screens had been visited. Event order was important because correct search depended on considering whether the object was still in the experimenter's hand after it had visited the first two screens but before it had visited the second two screens (parallel to the consideration in our search task to the need to consider the fact that the camera had been used at a specific point in the event series). In fact, even 3- and 4-year-olds were by no means at ceiling on this task, particularly on second searches. However, 3-year-olds were above chance on at least some types of trials.

The important difference between such tasks and our task seems to be whether or not children are aware in advance of the event sequence that they will need to search for the object. In Somerville and Capuani-Shumaker's (1984) task, children were able to keep track of the object's trajectory as it moved through the various locations and sequentially update their model or models of the object's location as events unfolded, albeit being required to do so without actually being able to continuously see the object. The relevant distinction here is that between sequential updating one's model of the world as events unfold (which is sufficient for passing invisible displacement tasks) and retrospectively engaging in temporal–causal reasoning, a distinction that is described in more detail by McCormack and Hoerl (2005). In our task, children are required to retrospectively reconstruct and reason about the order in which certain events have occurred precisely because they had not been tracking the relevant object's location.

One way to put this point is to consider whether the tasks necessarily involve representations that have past tense content. Arguably, in single invisible displacement tasks, the content of children's representations can always be described as present tense. For example, when the object in the experimenter's hand moves behind the occluder, the child needs to form the representation "The object is in location X." When the hand emerges, they need not update their representation (because the hand is empty); they can then use this representation as the basis for object search. What is distinctive, and perhaps more demanding, about double invisible displacement tasks is that these representations must allow for the possibility that the object is in more than one location (i.e., "The object is in either X or Y"). However, the issue of whether the object must be represented as currently being in one of two possible locations is distinct from the issue of whether representations with a past tense content are needed for task success. Because in double invisible displacement, children can actively keep track of the object's location as events unfold, their representations need only involve present tense content because such representations can be updated online as the display changes. Thus, although task success may depend on children's being able to represent the object as currently being in either one of two places, it need not require retrospective reflection on the order of past events. However, in our search task, because children are not aware that they need to maintain a representation of the object's possible location as the event sequence unfolds, task success depends upon considering what has happened in the past and, in particular, the order in which the events have happened.

Although we have argued that our task is importantly different from that of Somerville and Capuani-Shumaker (1984), 3-year-olds' difficulties on their task contrast with the successful performance of younger children on Haake and Somerville's (1985) task that was structurally similar but had a shorter event sequence. In the latter task, there were only two occluders, one before and one after the point at which children saw whether or not the object was still in the experimenter's hand. Experiment 3 was designed to investigate whether a reduction in the number of events/locations would also aid young children's performance on our search task. In this experiment, the number of cages in the zoo was reduced from five to three (see Figure 1b), meaning that there was now one location before the kangaroo and one after it. All other aspects of the tasks remained identical to that of Experiment 2. As 5-year-olds had consistently proven to be successful on the original version of the tasks, we chose to only examine the abilities of 4-year-olds on this simplified task.

Method

Participants

Sixty 4-year-olds were tested, 30 on the search task (M = 56 months, range = 51–59 months) and 30 on the planning task (M = 55 months, range = 48–59 months). There were 34 girls and 26 boys. Five other children were tested but were excluded from the analysis as they answered one or more of the control questions incorrectly. All children were of Caucasian descent, except for one who was of Black descent and one who was of Asian descent. These were primarily of middle-class background. All the children attended schools close to the authors' university. Children were tested in a quiet area of the school and received a set of stickers for taking part.

Materials

The materials were identical to those used in Experiment 2, except that there were now only three cages used rather than five and, consequently, two lockers instead of four. The kangaroo was again always at the middle location, which was now Location 2 along the path.

Procedure

This was identical to that used in Experiment 2.

Results and Discussion

In the three-event/location version of the tasks, there was now only one right and wrong answer for each task. Two-tailed binomial analysis showed that 4-year-olds once again failed the planning task ($p >$ .05). However, 4-year-olds performed above chance on the search task ($p <$ .05). The difference in performance between the two tasks approached significance, $\chi^2(1) = 3.59$, $p = .06$. Thus, the results showed that 4-year-olds were able to pass a simplified version of the search task. It would appear that the reduction in the number of events/locations from five to three aided children's performance in this task. This modification of the task made no difference to children's performance on the planning task, however. Children of this age failed even this simplified version of the planning task.

Thus, the key finding of this experiment is that simplifying the event sequence had a different effect on the two tasks: improving performance on search but not on planning. As with Experiment 1, it is necessary to consider why there might be a disparity between the findings of the tasks assessing reasoning about past and future event sequences. One possible difference between the tasks may lie in the salience of event order information—information that is crucial for passing the task. In the search task, children have viewed the events in a specific sequence, and existing research on children's order memory would suggest that they should be able to remember this order (summarized in Friedman, 2003). In contrast, in the planning task, children are merely told about events that will occur in a specific sequence and may neglect order information in their reasoning even though they can answer memory control questions correctly.

Experiment 4

This experiment had two aims. First, we wished to replicate the findings of Experiment 3 in which children were successful on the simplified search but not the planning task. Second, we wanted to examine whether cueing children to focus on the information necessary to correctly answer the test questions would assist performance. Previous research using more complex planning tasks suggests that cues or external guidance can aid children's performance (e.g., Hudson & Fivush, 1991). Povinelli et al. (1999) also found that 5-year-old children could succeed on their temporal–causal reasoning task whenever the order in which the two causally relevant events occurred was emphasized, whereas without such cues, the group failed to perform at above-chance levels. However, McCormack and Hoerl (2005) found that the provision of cues did not improve 4-year-olds' performance on their temporal–casual reasoning task

In Experiments 2 and 3, children had been asked memory control questions after the test question. It was decided that asking such control questions might act as sufficient cues, if they were asked before the test question and framed in such a way that the child was made to reflect on this information. Although 4-year-olds in Experiments 2 and 3 could remember the appropriate pieces of information, it does not necessarily follow that they attended to them during the task. It was hoped that questioning children about this information immediately prior to being asked the test question would make these pieces of information particularly salient.

Method

Participants

Participants were sixty 4-year-olds, 30 tested on the search task ($M = 55$ months, range = 50–59 months) and 30 on the planning task ($M = 54$ months, range = 48–59 months). There were 31 boys and 29 girls. These children attended nursery schools local to the authors' university and were tested individually in a quiet room in the nursery. All were of Caucasian descent. Children received a set of stickers for taking part.

Materials

These were identical to those used in Experiment 3.

Procedure

The tasks followed the procedure of Experiment 3 except that the memory control questions were now asked before the test question instead of after it. In the search task, before the test question, the experiment said: "Let's now think about where the camera must be. Do you remember what animal Molly took a photo of? That's right, look here's the photo of the kangaroo. And what way did Molly go round the zoo? That's right." In the planning task, before asking the test question, the experimenter said: "Let's think about where we should put the camera so that Molly can take a photo of the kangaroo. What way does Molly have to go round the zoo? That's right. And what animal does Molly want to take a photo of? That's right." The order in which the control questions were asked was counterbalanced.

Results and Discussion

Initial analyses showed that the order in which the memory control cues were asked did not influence children's performance. Two-tailed binomial tests showed that 4-year-olds again passed the search task ($p < .01$). However, as a group, they failed the planning task ($p > .05$). Analyses comparing these results with those of Experiment 3 showed that there was no significant improvement in 4-year-olds' performance in either the search task, $\chi^2(1) = 0.1$, $p > .05$ or the planning task, $\chi^2(1) = 0.27$, $p > .05$. The results of this study closely replicated those of Experiment 3, in that 4-year-olds passed a simplified version of the search task but not the planning task. Although children passed the search task, they were not at ceiling as a group and performed at a very similar level to the 4-year-olds in Experiment 3. Thus, making children explicitly attend to the relevant information did not improve children's ability on either task compared to when they had to spontaneously recruit that information. In this sense, these findings are consistent with those of McCormack and Hoerl (2005). However, the finding in Experiments 3 and 4 that 4-year-olds can pass the simplified search but not the planning task stands in direct contrast to the findings of Experiments 1 and 2 in which children of this age group failed both tasks.

The consistency of the findings of Experiments 3 and 4 suggests a reliable difference between children's performance on the search and planning tasks on this simplified version of the tasks. This difference suggests that although 4-year-olds may be able under some circumstances to make temporal–causal inferences for past events, they have more difficulties when the events in question are in the future. The findings of the first three experiments raise two important issues: (a) why do children younger than 5 years have difficulties with the planning but not the search task and (b) why do 4-year-old children find the three-event/location search task easier than the five-event/location task? These two issues were explored in Experiments 5 and 6, respectively.

Experiment 5

The previous studies have shown that 4-year-olds fail the planning task even when the event sequence has been simplified and when they have been specifically cued to the relevant pieces of information. One obvious difference between the search and planning tasks lies in the extent to which imagination is required in both. In the search task, children have observed the sequence of past events that they must reason about, whereas in the planning task, children must imagine and reason about never-before-experienced events taking place in an unknown future. Harris (2000) has convincingly argued that research on children's play and pretense suggests that the causal implications of imagined actions or events are grasped from an early age, and others have suggested that children may possess the imaginative abilities necessary for simple planning relatively early in development (Haith, 1997). However, play and pretense usually involve imagining versions of events or actions that are in many ways already familiar to children. Furthermore, imagining the causal consequences of a single imagined act is likely to be more developmentally primitive than grasping the significance of the temporal order of a sequence of imagined events. The current task was designed so that it involved a novel event sequence, and it required children to mentally construct a sequence of future events while bearing in mind a novel goal.

In Experiment 5, we examined whether it might be possible to boost children's performance by making this imaginative project easier. Previous research on children's planning across a variety of tasks has suggested that provision of goal state information may aid performance (Bauer et al., 1999; Shapiro & Hudson, 2004; Welsh, 1991). In Experiment 5, children were actually provided with a concrete example of the goal in the task—namely, to obtain a photograph of the kangaroo. In the search task, a photograph of the kangaroo was present throughout the testing phase. In Experiment 5, the test procedure was altered so that the planning task resembled the search task in this respect. Children were told that another doll had already been to the zoo prior to Molly and taken a photo of the kangaroo, which they were then shown. They were then informed that Molly also wanted to take a photo of the kangaroo. This photo of the kangaroo remained present throughout the task. If 4-year-old children perform successfully on this version of the planning task, it might suggest that their failure of the task in Experiments 1–3 was due to the particular demands of imagining a novel goal state when thinking about the future in contrast to reasoning about a known past.

Method

Participants

Thirty 4-year-olds ($M = 53$ months, range = 48–59 months) completed this version of the planning task. There were 13 boys and 17 girls. Three additional children were excluded from the analysis because they failed to answer one or more of the control questions correctly. Participants were mostly from working- and middle-class backgrounds and all were of Caucasian descent. All children attended a nursery school local to the authors' university. Children were given a set of stickers for participating. None of these children had taken part in previous experiments.

Materials

These included the same materials that had been used in the planning task in Experiments 3 and 4. In addition, there was another doll, Molly's sister Rosie. This was of similar size and shape to the first doll. A green felt rucksack (of the type used in the previous search tasks) was also used in the introductory phase of the task. Inside this was placed another Polaroid camera identical to the one used by Molly. This bag also contained a photo of the kangaroo that had been taken by the Polaroid camera.

Procedure

After the initial familiarization phase, children were told that Molly had a sister, Rosie, who had already been to the zoo. They were shown this doll, which had a bag on its back containing the Polaroid camera and the photo of the kangaroo. The camera was taken out of this doll's bag, and children were told that Rosie also had a camera, which she took to the zoo with her. They were shown that this camera was the same as Molly's. They were informed that Rosie had taken a photo of the kangaroo when she had been at the zoo, and they were shown the photo. This was then placed in front of the kangaroo's cage, directly facing children, where it stayed for the remainder of the task. Children's attention was then drawn to Rosie's bag, and the experimenter told them that Rosie had carried her camera in this bag. They were then told that Molly did not have a bag with her and so could not carry the camera round the zoo. From this point onward, the procedure was identical to that used in Experiment 3.

Results and Discussion

As can be seen in Table 1, the modification of the task did not improve 4-year-olds' performance. This group again failed to perform at a level significantly above chance ($p > .05$, two-tailed binomial). Thus, children's failure of this task appears to be a robust phenomenon. Children of this age could still not make the correct inference even when they were provided with a visually available example of the goal state in the task. This provides some indication that younger children's problems on the planning task may not be due to imagining a novel goal state. Children's persistent difficulties on this task contrast with their good performance on the simplified search task in

Experiments 3 and 4 and force a consideration of the differences between reasoning about the past and the future.

Experiment 6

Experiments 3 and 4 showed that 4-year-olds can pass a simplified version of the search task involving a reduced number of events/locations, whereas they are unsuccessful on the five-event/location version. There are at least two clearly separable explanations of why reducing the number of events/locations might improve children's performance. One of these is to do with the presence of multiple possibilities. In the task used in Experiments 1 and 2, there were two possible right answers: The camera could have been lost at either the fourth or fifth location. Both of these were equally likely to be the true location of the camera. Children were only allowed to search in one location, however, and so had to choose between them. Being forced to choose between them may have adversely affected younger children's performance because of the inherent ambiguity over which location is correct. The second possible type of explanation of the improved performance in the search task in Experiments 3 and 4 relates directly to the actual number of events and locations used in the task rather than to the number of possible correct answers. Arguably, the array is more visuospatially complex when there are more locations, and there are greater number of events to represent. Reducing the number of events/locations in itself may mean that the task has a reduced processing load.

The first explanation is quite different from the second and implicates a fundamental problem with reasoning when there are multiple possibilities rather than an excessive demand on cognitive processes. Recent empirical research has shown that younger children consider multiple possibilities or ambiguity differently from older children and adults (Beck, Robinson, Carroll, & Apperly, 2006; Robinson, Rowley, Beck, Carroll, & Apperly, 2006; though see Sophian & Somerville, 1988). This research indicates that 4-year-olds may not realize that multiple possibilities exist, or consider them in their reasoning, rather than the presence of multiple possibilities interfering with their reasoning skills. However, it is possible that problems reasoning in a task in which there is more than one possible correct answer produced difficulties for children in the search task used in Experiments 1 and 2. In Experiment 6, 4-year-olds were given a five-event/location search task in which there was only one correct answer. In the new configuration, there were five locations/events, as in Experiments 1 and 2, but three of these were before the kangaroo and only one after it (Figure 1c). Thus, as in Experiments 3 and 4, there was a single location in which the camera could logically be. If 4-year-olds were successful on this task, then this would suggest that it was something to do with having more than one correct location (i.e., difficulties dealing with multiple possibilities) that disrupted children's ability to make the appropriate inferences in Experiments 1 and 2.

Method

Participants

Thirty 4-year-olds were tested on this version of the search task ($M = 53$ months, range = 49–58 months). There were 13 boys and 17 girls. Two additional children were tested but were not included in the analysis as they gave the wrong answer to one or more of the control questions. All children were of Caucasian descent and were from mainly working- and middle-class backgrounds. Participants were drawn from nursery schools local to the first author, and testing took place in a quiet part of the nursery in a room suitable for testing purposes. Children received a set of stickers for taking part. None of the children had taken part in any of the previous experiments.

Materials

The materials that had been used in the original version of the search task in Experiment 2 were again utilized in this study, arranged as illustrated in Figure 1c.

Procedure

The procedure was identical to that of Experiment 2.

Results and Discussion

In this study, Locations 1, 2, and 3 were scored as incorrect, whereas Location 5 was correct; Location 4 was the kangaroo's cage and thus not a possible choice. Children's location responses are shown in Table 2, with correct answers shown in bold. It can be seen that exactly half the group chose the correct location, whereas the other half chose one of the other three locations. If a binomial test proportion of .5 is used, with children's answers categorized dichotomously as correct and incorrect, then the group can be interpreted as failing to choose the correct location significantly more often than would be predicted by chance ($p = 1.00$). However, there are four locations, and if it is assumed that each has a one in four chance of being chosen, then a binomial test proportion of .25 should be employed (this issue did not arise in previous analyses because exactly half of the locations were always correct or incorrect). Such an analysis showed that children chose Location 5 (the correct answer) significantly more frequently than any other location ($p < .01$). Thus, even though a majority of children did not answer correctly, it might be argued that nevertheless the group as a whole was not responding at random. In order to interpret this nonrandom performance, we compared children's location choices in this task with those in the search task in Experiment 2. The rationale for this comparison was that if it is the case that children's nonrandom performance in this experiment should be interpreted in terms of task competence, then their performance should differ significantly from that in the version of the task used in Experiment 2 in which the locations had a different status. The analysis showed that location choices in this task did not in fact differ significantly from those in Experiment 2, $\chi^2(3) = 5.38$, $p \geq .05$. Thus, despite there being only one correct answer, this age group still failed the task. This suggests that it was not the ambiguity created by having more than one possible correct location that was responsible for the difference in performance between the three- and five-location search tasks. Rather, 4-year-olds' success on the simplified version of the task appears to be a direct result of reducing the number of events/locations.

General Discussion

The aim of this research was to investigate a particular type of mature temporal thinking—temporal–causal reasoning—that involves reasoning about the causal significance of the temporal order of events (McCormack & Hoerl, 2005, 2007; Povinelli et al., 1999). The search and planning tasks allowed us to examine the development of this type of thinking for both past and future sequences of events. Taken as a whole, the findings suggest that by 5 years, children can reason about the causal relations between temporally ordered events for both the past and the future. By contrast, 3- and 4-year-olds failed the original versions of both the search and the planning tasks, even when the response mode was changed to discourage unproductive search strategies (Experiments 1 and 2). Memory checks ensured that this failure was not due to a difficulty remembering the necessary pieces of information to make the appropriate inferences (Experiment 2). These initial results are consistent with the previous research in this area (McCormack & Hoerl, 2005, 2007; Povinelli et al. 1999), despite very different methodologies.

Search

Although 4-year-olds were not above chance on the search task in Experiments 1 and 2, they were successful on a simplified version of the search task in which there were only three events in the sequence and only one possible correct answer (Experiments 3 and 4). This finding raises two closely related questions: (a) why does simplifying the task in this way lead to improved performance and (b) what do the findings tell us about the development of this type of reasoning? The first question was addressed in Experiment 6, in which the number of events/locations was identical to that used in the first two experiments (i.e., five), but the array was altered so that there was only one possible correct response. Four-year-olds were unsuccessful in this version of the task, which suggests that reducing the overall number of events/locations in Experiments 3 and 4 in itself improved performance on our search task rather than the elimination of the possibility of more than one correct response. This interpretation of the findings is consistent with the findings of Collier-Baker and Suddendorf's (2006) recent study of double invisible displacement. They found that under some conditions, 2-year-olds could appropriately direct their second searches if they failed to find the object on a first search, indicating that under some circumstances, even much younger children find the presence of more than one correct response unproblematic.

The second question forces a consideration of whether we should conclude that children younger than 5 years are capable of making appropriate temporal–causal inferences when the task is sufficiently simple. Such a conclusion could be interpreted as inconsistent with the findings of Povinelli et al. (1999) and McCormack and Hoerl (2005, 2007), as children of this age had consistent problems in their tasks. We have argued that the nature of our task makes it possible to straightforwardly interpret it as assessing this type of reasoning, in contrast to various earlier studies of children's search behaviors that were not designed for that purpose (e.g., those of Anooshian et al., 1982; Haake et al., 1980; Wellman et al., 1979). For example, we have ensured that children's searches did not simply reflect basic associative processes or that failure was not due to memory problems. The spatial layout, even in Experiments 1 and 2, was also simple. However, the fact that 4-year-olds passed the task only when the spatial layout was further simplified (Experiments 3 and 4) might in itself suggest a way of reconciling our findings with those of Povinelli et al. and McCormack and Hoerl (2005, 2007). Specifically, perhaps children succeeded on some versions of the task precisely because it had a spatial component.

In designing the tasks, it was hoped that mirroring temporal order in spatial order would support children's sequence memory and ensure that they did not fail the task because they had forgotten the order in which events had occurred. It may be the case that making temporal order concrete in this way—by spatializing it and making it visually available—supports 4-year-olds' inferences concerning temporal order. In particular, if the spatial layout is very simple, as in Experiments 3 and 4, then the fact that temporal order is in some sense visually available may assist 4-year-olds in making an appropriate inference. In summary, the findings suggest that there may be some circumstances under which 4-year-olds are able to make temporal–causal inferences about past events and these may include circumstances in which temporal order is mirrored in a simple spatial display.

Planning

Five-year-olds' consistent success on the planning task in Experiments 1 and 2 demonstrates that by this age, children can construct a plan concerning a completely novel event sequence, taking into account the order in which events will occur. However, 4-year-olds consistently failed the planning task even when the number of events in the sequence was reduced and even when they were asked to recall the pieces of information necessary to make the correct inference immediately before the test question (Experiment 4). As they stand, these findings are consistent with the previous research into young children's planning abilities, which has found a marked improvement in planning ability between the ages of 3 and 5 (Hudson et al., 1997; Wellman et al., 1985; Welsh, 1991).

Four-year-olds' passed neither the search nor planning tasks in Experiments 1 and 2. However, this age group passed the simplified search but not the planning task in Experiments 3 and 4. One possible difference between the two tasks is that reasoning about a completely novel sequence of future events may place greater demands on imagination than reasoning about a sequence of past events that has already been observed (see also Hudson et al., 1997). In other words, perhaps children's difficulties with planning on the task were primarily problems with generative imagination rather than reasoning per se. In Experiment 5, children were provided with an example of the goal state in the planning task in an attempt to make this imaginative project easier. This sort of visual support had been present during the test phase of the search task but not in the versions of the planning task used in Experiments 1–4. However, its provision in Experiment 5 did not lead to improved performance. Of course, it is possible to argue that there may be additional, more effective, ways in which the imaginative demands of the task might be reduced: For example, we could have actually shown the other doll travel round the zoo and take a photograph of the kangaroo. It may be the case that the fact that the event sequence was entirely novel made planning particularly difficult in this task. In designing future tasks, it may prove useful to distinguish between the imaginative demands of a planning task and the reasoning processes that it involves.

The Development of Temporal Cognition

We finish by turning to a consideration of the relationships between the type of ability we have studied and two other temporal abilities that have been the focus of research: MTT and temporal decentering.

MTT

The aim of our studies has been to examine the development of a particular type of temporal cognition that may be involved in reasoning about both past and future event sequences. There are at least three similarities between the type of temporal cognition we are concerned with and that which is the focus of researchers working on the development of MTT. First, in designing our tasks, we have attempted to ensure that children need to detach from the here and now and consider the implications of either what has happened at a specific point in the past or what will happen at a point in the future. Similarly, researchers working on MTT are trying to capture a type of cognition that involves mentally detaching from current events or concerns. Second, we are focusing on a cognitive ability that goes beyond the ability to bring to bear knowledge of familiar event sequences. Thus, our tasks require children to reason about entirely novel unfamiliar event sequences. Researchers working on MTT are also trying to pinpoint a type of cognition concerning specific past or future events (hence the term *episodic future thinking*; Atance & O'Neill, 2001a) and contrast this type of cognition with the ability to draw on semantic memory or on script-like memory (Atance & Meltzoff, 2005; Suddendorf & Busby, 2003). Third, because of this characteristic, both temporal – causal reasoning and MTT are thought to be flexible and insightful types of cognition—for example, the type of planning for the future that they involve is not merely a matter of bringing to bear preexisting knowledge about what usually happens in such a situation or using a preestablished routine or strategy. Indeed, one way to think about the relationship between the two cognitive abilities is that MTT may deliver representations of specific past and future events, but frequently temporal – causal reasoning may be required to make use of the information given in such representations through a consideration of the causal connection between such events and other relevant events.

However, there are also important differences between the way that we conceptualize temporal – causal reasoning and how MTT has been characterized. It has been argued there is a distinctive phenomenology associated with the mental preexperiencing of past events and the imaginative preexperiencing of future ones that singles out MTT from other types of cognition concerning the past and the future (Suddendorf & Busby, 2003; Tulving, 2001). Furthermore, MTT is thought to be an essentially self-conscious activity involving one's personal past and future (Tulving, 2005). In contrast, we have defined temporal – causal reasoning without reference to subjective experience, and our experimental approach does not allow us to examine whether young children's thought about the past and future possesses the relevant distinctive phenomenology. For this reason, we would not wish to argue that the tasks used in our studies necessarily involve MTT. With regard to the involvement of self-consciousness, it is clear that the tasks do not involve either making plans that involve the self carrying out an action (Atance & O'Neill, 2001a, 2005; Suddendorf & Busby, 2005) or reflecting on one's personal past (Nelson, 2001; Perner & Ruffman, 1995). Clearly, the same basic sort of reasoning ability would be required if our tasks were set in contexts in which the actor were the child rather than a doll character. However, we do not know if the developmental trends and task effects that we have found would be replicated under such circumstances. Exploring such an issue is an important extension of this work.

Although our studies have clearly not addressed issues concerning subjective experience, there may still be conceptual connections to be drawn between temporal – causal reasoning and both self-consciousness and the phenomenology of thought about other times. For example, it has been argued elsewhere that possession of a mature concept of time may involve a grasp of the causal connections between events that occur at different times (Hoerl & McCormack, 2005; see also Martin, 2001), and it may be that possession of such a concept is a necessary developmental prerequisite for certain types of subjective experiences (McCormack & Hoerl, 2001). Furthermore, it may be the case that children initially acquire such a concept through reflection on the causal connections between events in their own personal past (Hoerl & McCormack, 2005; McCormack & Hoerl, 2001; see also Welch-Ross, 2001). Thus, although the sort of temporal – causal reasoning measured in our tasks is not a self-conscious activity, it may have its developmental origins in self-conscious reflection.

Temporal Decentering

Weist (1986, 1989) has suggested that the period between 3 and 5 years involves the emergence of temporal decentering, which he conceived of as the ability to think about events and the temporal relationships between them from a temporal perspective other than the present (see also Cromer, 1971, Harner, 1982; McCormack & Hoerl, 1999). Temporal decentering is viewed as a fundamental form of mature temporal cognition that applies to both the past and the future. Weist's account is based on a consideration of the ways in which children's temporal language changes during this developmental period. In some languages, children between 3 and 5 years begin to use complex tenses such as the past perfect tense, for example, "I had made the cake." Drawing on Reichenbach's (1947) analysis of tense, Weist suggested that use of such tensed forms indicates that children are able to flexibly coordinate at least three points in time—in the earlier example, the present time of utterance, the time at which the cake was made, and a subsequent time at which the cake had already been made. He argued that the coordination of three separate points in time is a hallmark of flexible temporal decentering. Attempts to examine such abilities experimentally have looked at whether children can match tensed sentences to appropriate points in an illustrated event sequence (Cromer, 1971; Harner, 1980).

Our tasks deliberately placed minimal demands on temporal language. However, arguably they assess a similar ability to that described by Weist as temporal decentering because they involve children having to consider the relationship between three points in time: the current time, the time at which the photograph has been or will be taken, and the time at which the camera was lost or will be collected. Weist (1989) has also argued that between 3 and 5 years, children begin to properly master the terms *before* and *after* (Harner, 1980; Trosborg, 1982), and that such mastery is further evidence of the development of flexible temporal decentering and mature temporal cognition. Although the terms *before* and *after* were not used in our tasks, successful performance depended on children in the search task realizing that they need to search in locations visited after the camera had been used and children in the planning task realizing that they needed to put the camera in a location to be visited before the camera was required. It would be interesting to explore whether success on the tasks is related to children's comprehension of temporal terms such as *before* and *after*, and more generally to children's mastery of temporal language.

Conclusions

Theorists describing cognitive abilities such as MTT have suggested that thinking about the past and the future recruit a common cognitive skill. We have argued that this is true, but we have characterized such a skill as involving a certain type of reasoning ability rather than in terms of a certain type of consciousness. Although the requirements of the two temporal – causal reasoning tasks used in these studies were not identical, a strength of the experimental method is that it provides a context in which differences between reasoning about the past and the future could be discovered and explored. Our results suggest that although thinking about the past and future both require an appreciation of the causal significance of the temporal order of events, there may be additional requirements specific to thinking about the future. Furthermore, with regard to both the past and future and in line with previous findings and theoretical claims (Atance & O'Neill, 2005; Friedman, 2005; McCormack & Hoerl, 2005, 2007; Povinelli et al., 1999; Suddendorf & Busby, 2005), we have found developmental changes that suggest a fundamental change in temporal cognition between 3 and 5 years.

Effects of Family Violence on Psychopathology Symptoms in Children Previously Exposed to Maltreatment

Andrea Kohn Maikovich and Sara R. Jaffee

Candice L. Odgers
University of California, Irvine

Robert Gallop
West Chester University

Although many studies suggest that family violence is associated with child psychopathology, multiple features of the home environment might account for this association, such as poverty and caregiver psychopathology. Studies are needed examining how change in psychopathology symptoms is affected by home violence, controlling for children's own developmental symptom histories and other predictors of psychopathology. This study used latent difference score structural equation modeling to test if witnessing home violence and/or experiencing harsh physical discipline predicted changes in psychopathology symptoms among 2,925 youth aged 5 – 16 years previously exposed to violence. Results demonstrated that harsh physical discipline predicted child-specific changes in externalizing symptoms, whereas witnessing violence predicted child-specific changes in internalizing symptoms across time. Implications for research and policy are discussed.

Many American children are exposed to violence in their homes. The U.S. Department of Health and Human Services, Administration for Children and Families, Children's Bureau (2005) reported that child protective service (CPS) agencies receive over 50,000 reports of suspected child maltreatment each week. After reviewing the available literature, Straus et al. (1998) concluded that approximately 5% of children are the victims of severe physical assault and that rates of physical abuse are potentially much higher depending on the exact definition of abuse utilized in any given study. These researchers also concluded that at least one in six American couples have engaged in partner-against-partner assault, and Straus (1992) estimated that 10 million American children witness domestic violence in their homes each year. Many children experience both forms of family violence (Slep & O'Leary, 2001). The majority of studies reviewed by Edleson (1999) found 30% – 60% co-occurrence rates, and several additional studies and reviews have also reported high rates of overlap (e.g., Appel & Holden, 1998; Moffitt & Caspi, 1998).

A plethora of studies now provide compelling evidence that children who are maltreated and children who witness family violence (e.g., adult partner violence) are at increased risk of psychopathology compared with children who are not exposed to violence (e.g., Jouriles, Murphy, & O'Leary, 1989; Kaplan, Pelcovitz, & Labruna, 1999; Kernic et al., 2003; Trickett & McBride-Chang, 1995; Wolfe, Crooks, Lee, McIntyre-Smith, & Jaffe, 2003). Jaffe, Wolfe, Wilson, and Zak (1986) found that abused boys and boys who had witnessed domestic violence had similar adjustment problem patterns and that both groups of boys had significantly more problems than a control group. In a recent meta-analysis, Wolfe et al. (2003) concluded that children who were both abused and exposed to domestic violence had higher levels of emotional and behavioral problems than did children who had only been exposed to domestic violence. Thus, children who are both victimized by violence and who witness domestic violence may be particularly vulnerable to developing psychopathology symptoms and are therefore an important population to study.

The extant literature suggests that there are several direct links between physical abuse and negative

child outcomes. For example, children who are physically abused are more likely to encode violence as an acceptable interaction strategy (Black & Newman, 1996) and have deficits in their attention self-regulatory abilities that cause them to overattend to anger cues (Shackman, Shackman, & Pollak, 2007). There are also indirect links between physical abuse and negative child outcomes. Abuse of a child is often associated with a host of suboptimal parenting practices that in and of themselves contribute to increases in children's internalizing and externalizing symptoms (e.g., Belsky, 1993; Burgess & Conger, 1978). For example, compared with nonabusive parents, abusive parents engage in significantly fewer positive interactions with their children, have interactions that more frequently contain angry and punitive statements, and interact less often with their children (Burgess & Conger, 1978; Vasta, 1982). Other researchers have found that nonabusive parents are more likely to use reasoning and simple commands and to choose disciplinary techniques that match the child's misbehavior, whereas abusive parents nearly always utilize punitive disciplinary techniques even for very minor child misdeeds (Trickett & Kuczynski, 1986).

Parenting practices and children's well-being might also be affected by the relatively high rates of stress and mental health problems that adult victims of family violence experience (Farver, Crooks, Lee, McIntyre-Smith, & Jaffe, 2005; Margolin & Gordis, 2000). For example, Farver et al. (2005) showed that the association between family and community violence and children's depressive symptoms was partially mediated by mothers' depressive symptoms. Furthermore, Wolfe, Crooks, Lee, McIntyre-Smith, and Jaffe (1985) found that the association between witnessing violence and children's problems was at least partially mediated by maternal stress and associated factors, and Holden and Ritchie (1991) found that maternal stress and paternal irritability were the two major predictors of behavior problems in children of battered women. Maternal depression may contribute to children's internalizing and externalizing symptoms by making mothers less consistently supportive and reliable caregivers (Katz & Gottman, 1997).

Although parenting problems might be one pathway by which family violence increases risk for child psychopathology, children who are exposed to violence are also likely to experience many other stressors that. are associated with elevated rates of psychopathology such as poverty, community violence, and poor schools (Hay & Jones, 1994; National Research Council, 1993). Even if families and children receive social services, children's homes frequently remain chaotic and violent, even if not sufficiently "abusive" to merit further action by CPS. The multiple stressors and risk factors for psychopathology that are associated with violence in the home need to be accurately measured and accounted for in research studies in order to isolate the effects of abuse and witnessing violence, as the association between family violence and children's problem behaviors may be accounted for by social disadvantage more generally.

Moreover, although family violence may lead to symptoms of depression, anxiety, substance use, or aggression in adult victims and perpetrators, adults who have histories of mental health problems and behavior problems are more likely to form relationships that become physically and psychologically abusive (Magdol, Moffitt, Caspi, & Silva, 1998). They are also more likely to abuse their children (Bland & Orn, 1986a, 1986b; Egami, Ford, Greenfield, & Crum, 1996). This implies that the effects of family violence on child well-being may be genetically mediated. Given that adult depression, anxiety, substance use, and antisocial behavior are all moderately heritable (McGuffin, Owen, & Gottesman, 2002), it is possible that family violence is merely a marker for genetic risk for psychopathology that parents transmit to children (DiLalla & Gottesman, 1991; Jaffee, Caspi, Moffitt, Taylor, & Arseneault, 2002, 2004).

In this study, we examined how the levels of violence children reported witnessing in their home and the amount of harsh physical discipline caregivers reported using with their children were associated with changes in the externalizing and internalizing symptoms of children previously exposed to violence. We hypothesized that both harsh physical discipline and witnessing violence would be associated with changes in externalizing and internalizing symptoms above children's expected trajectories in this sample of children previously exposed to violence. Externalizing and internalizing behavior problems typically decline from childhood to adolescence, although some children maintain consistently high levels of problem behaviors (Broidy et al., 2003; Chang, Halpern, & Kaufman, 2007). One goal of our study was to test whether reexposure to violence would account for individual differences in children's trajectories and explain why some children do not show the expected decline in problem behaviors.

Our study attempted to redress several methodological limitations of previous studies in this field. First, whereas many studies examine physical violence against children or adult domestic violence, these forms of violence tend to co-occur. Therefore, we estimate the unique effect of each type of violence on children's mental health. Second, whereas many studies estimate the concurrent or prospective associations between family violence and child psychopathology, our study examines the relationship between family violence and change over time in children's symptoms. This allows us to get a better handle on the direction of the relationship between family violence and children's problem behaviors and is a better test of whether family violence is a potential cause of children's psychopathology.

Method

Subjects

The National Survey of Child and Adolescent Well-Being (NSCAW) is a nationally representative sample of U.S. children who have had contact with CPS (Dowd et al., 2004). The full cohort includes 5,501 children (50% female), younger than 1 year to 16 years when first sampled, who were subjects of child abuse or neglect investigations conducted by CPS agencies from October 1999 to December 2000. The sample was selected using a two-stage stratified sample design. At the first stage, the United States was divided into nine sampling strata. Eight strata corresponded to the eight states with the largest child welfare caseloads, and the ninth stratum consisted of the remaining 38 states and the District of Columbia. Within each of the nine strata, primary sampling units (PSUs) were formed and randomly selected. PSUs were defined as geographic areas that encompassed the population served by a single CPS agency (e.g., counties). At the second stage, equal numbers of children were selected from each PSU, regardless of PSU size. Children were selected from eight mutually exclusive and exhaustive domains such that the final sample adequately represented relevant combinations of (a) infants versus children aged 1–14 years, (b) children receiving CPS-funded agency services versus children receiving no services, (c) children in out-of-home care versus children not in out-of-home care, and (d) children who were investigated for allegations of sexual abuse versus other forms of abuse or neglect. Additional information about the sample composition is available from Dowd et al. (2004).

Field staff completed 12 days of training on the protocol. At baseline (Wave 1), face-to-face interviews or assessments were conducted with children, their caregivers (e.g., biological parents, foster parents, custodial kin caregivers), their teachers (when children were of school age), and their caseworkers (when applicable). Follow-up interviews were conducted at 12, 18, and 36 months postbaseline. (Only the data from the first, third, and fourth waves of data collection were used in this article, as the data collection protocol was significantly different for the second wave.) Current caregivers were paid $50 for their participation and children were given gift certificates worth $10–$20.

The current analyses were restricted to children who were 5 years or older at Wave 1 (N = 2,925; 53% female) because younger children did not report on witnessing home violence. The racial/ethnic makeup of our sample was 46% White (non-Hispanic), 30% Black (non-Hispanic), 17% Hispanic, and 8% other races or ethnicities. Caseworkers reported on all subtypes of maltreatment children experienced and also designated the most serious type of maltreatment children experienced based on their review of the children's files and their ratings of the frequency, severity, and duration of each alleged or substantiated instance of abuse or neglect. For 40% of children, the most serious type of abuse was neglect; for 26%, it was physical; for 18%, it was sexual; for 9%, it was "other"; and for 8%, it was emotional. Within our sample, 34% of children experienced multiple types of maltreatment, and 62% of cases were substantiated. The mean child ages were 9.63 years (SD = 2.98) at Wave 1, 10.94 years (SD = 3.01) at Wave 3, and 12.24 years (SD = 2.99) at Wave 4.

Measures

Descriptive statistics are found in Table 1.

Externalizing symptoms. At each wave of data collection, caregivers were administered the Child Behavior Checklist (CBCL; Achenbach, 1991), which

Table 1
Descriptive Statistics for Variables Included in the Latent Difference Score Models

	M	*SD*	Range
Externalizing symptoms, baseline	16.13	11.52	0–60
Externalizing symptoms, 18 months	15.14	11.13	0–60
Externalizing symptoms, 36 months	14.59	11.14	0–65
Internalizing symptoms, baseline	10.40	8.67	0–58
Internalizing symptoms, 18 months	9.72	8.35	0–47
Internalizing symptoms, 36 months	9.48	8.09	0–54
Witnessed violence, baseline	3.57	2.72	0–12
Witnessed violence, 18 months	3.15	2.56	0–12
Witnessed violence, 36 months	2.80	2.55	0–12
Physical discipline, baseline	6.80	11.18	0–142
Physical discipline, 18 months	4.94	9.65	0–87
Physical discipline, 36 months	3.87	8.08	0–94
Income[a]	2.82[a]	1.41	1–5
Caregiver mental health	48.48	11.16	12–70
Child age, baseline	9.63	2.98	5–16

[a] Income was recoded such that 2 = $10,000–19,999 per year; 3 = $20,000–29,000 per year.

consists of 113 questions on a 3-point Likert-type scale (0 = *not true*, 1 = *somewhat or sometimes true*, 2 = *very true or often true*). We used the child's score on the CBCL Externalizing scale (which taps delinquent and aggressive behavior) as our measure of externalizing symptoms. Internal consistency reliability was high for this scale (α = .92). At each wave of analysis, 33%, 30%, and 28% of children had clinically significant externalizing scores, respectively (i.e., *t* scores at or above 65; Achenbach, 1991).

Internalizing symptoms. We used children's scores on the Internalizing scale of the CBCL (which comprises withdrawn behavior, somatic complaints, and anxious/depressed domains) as our measure of children's internalizing symptoms. Internal consistency reliability was high for this scale (α = .90). At each wave of analysis, 25%, 18%, and 17% of children had clinically significant internalizing scores, respectively (i.e., *t* scores at or above 65; Achenbach, 1991).

Witnessed violence. Children were administered the Violence Exposure Scale for Children (Fox & Leavitt, 1995), during which they were asked 23 questions regarding their exposure to violence and criminal events. Children younger than 11 years were also shown a cartoon depiction of each act, and all children were asked how often they had witnessed each act *at home* (never, once, a few times, or lots of times). They were then asked if they had witnessed the act in the past month (1 = *yes*, 2 = *no*). Internal consistency on this measure ranged from αs = .72 to .86 in a sample of inner-city minority preschool children (Shahinfar, Fox, & Leavitt, 2000).

In two-factor analyses, Raviv et al. (2001) and Raviv, Shimoni, Fox, & Leavitt (1999) identified a "mild" and a "severe" violence categorization scheme for the items on this measure. There were six types of violent acts that loaded onto the *witnessing mild violence* category. These included observing an adult yell at someone, observing an adult throw something at another person, watching an adult push or shove someone, watching an adult slap someone, observing an adult beat someone up, and observing another child getting spanked. The six items that loaded onto the *witnessing severe violence* category included observing a person steal things from another person, seeing an adult point a knife or gun at someone, observing someone stab another person, seeing someone shoot another person with a gun, observing someone getting arrested, and seeing someone deal drugs. We summed the number of different types of incidents children reported witnessing in the past month to create a total witnessed violence scale. Thus, children received a score between 0 and 12. In the NSCAW sample, internal consistency was high for the total score (α = .96). Across waves of data collection, between 71% and 80% of children did not witness any of the severe violence category events.

Caregiver use of harsh physical discipline. Caregivers were administered the Parent–Child Conflict Tactics Scales (CTSPC; Straus et al., 1998), which ask caregivers how often they used 22 disciplinary practices in the past year (0 = *never or not in the past 12 months*; 1 = *1 time*; 2 = *2 times*; 4 = *3–5 times*; 8 = *6–10 times*; 15 = *11–20 times*; 25 = *more than 20 times*). We used the caregivers' total score on the physical assault scale as our measure of harsh physical discipline, after dividing the total score by 10 in order to make the scale commensurate with that of our other variables. Examples of items on this scale range from spanking children with a bare hand to choking children. In the NSCAW sample, internal consistency for the measure was α = 0.92. Across waves of data collection, 86%–91% of children did not experience any of the "severe" or "very severe" physical discipline category events, so scores on this measure primarily reflected corporal punishment as opposed to physical abuse.

Income. Families were classified into five categories based on total family income in 1 year (1 = $0–$9,999; 2 = $10,000–$19,999; 3 = $20,000–$29,000; 4 = $30,000–$39,999; 5 = $40,000 and over).

Caregiver's mental health. Caregivers were administered the short-form health survey (Ware, Kosinski, & Keller, 1998), which assesses mental and physical health. We used the mental health subscale as our measure of caregiver mental health. This subscale has been shown to differentiate groups known to differ in terms of the presence and seriousness of their mental health problems (Ware, Kosinski, & Keller, 1996). Some of the questions on this subscale asked caregivers how often they felt a certain way, such as "downhearted or blue," and others asked how much emotional problems interfered with their daily life and social functioning (1 = *all the time*; 2 = *most of the time*; 3 = *a good bit of the time*; 4 = *some of the time*; 5 = *a little of the time*; 6 = *none of the time*). Caregivers were asked to respond to all questions based on their experiences during the past month. Age- and gender-standardized scores were created, with higher scores indicating better mental health. Internal consistency for the mental health scale in the NSCAW sample was acceptable (α = .79).

Results

Statistical Analyses

In this study, we used a series of latent difference score (LDS) models (Hamagami & McArdle, 2001;

King et al., 2006) to examine our hypothesis that witnessing violence in the home and being subjected to harsh physical discipline would predict changes in the externalizing and internalizing symptoms of children previously exposed to violence. LDS modeling has recently been put forward as an innovative methodological approach for advancing the longitudinal study of trauma (King et al., 2006). LDS models are part of a larger family of longitudinal structural models designed to assess growth and change and offer an advantage over traditional change score approaches by partitioning the true score from the error variance in a time series and producing an optimally reliable latent change score over assessment points. In the present study, LDS models provide a dynamic means of testing whether violence exposure predicts changes in children's psychopathology symptoms across time. The structural equation modeling (SEM) framework adopted here also offers the advantage of accounting for the nonindependence of children's violence exposure over time, and allows us to address the question of whether violence exposure predicts *changes* in children's psychopathology symptoms, after accounting for children's prior symptoms and other key predictors of psychopathology.

The analyses proceeded in three steps. The same steps were followed for both externalizing and internalizing symptoms. First, a baseline LDS model was fit to the data to derive the latent symptom change scores. Second, we built on the baseline models to investigate whether witnessing violence in the home and/or experiencing harsh physical discipline predicted changes in children's externalizing and internalizing symptoms relative to their own developmental histories after accounting for other important child and family risk factors for psychopathology. Third, we ran multiple group models to examine whether children's previous exposure to physical abuse moderated the relationship between violence exposure and changes in psychopathology symptoms.

Models were estimated using Amos version 5.0 (Arbuckle, 2003). In order to evaluate model fit, we used the model chi-square test; however, because the interactive effect of sample size and model error on this test typically causes the model chi-square to be statistically significant with large samples even when the model represents a close fit to the data (MacCallum, 1990), we employed three additional fit indices: the comparative fit index (CFI; Bentler, 1990), the Tucker–Lewis index (TLI; Tucker & Lewis, 1973), and the root mean square error of approximation (RMSEA; Steiger, 1990). Model chi-square values with accompanying p values greater than .05 indicate a good model fit. CFI and TLI values greater than 0.95 and RMSEA values less than 0.05 indicate a good fit; CFI and TLI values between 0.90 and 0.95 and RMSEA values between 0.05 and 0.08 indicate an acceptable fit. (For a discussion of the various fit indices, see Browne & Cudeck, 1992; Medsker, Williams, & Holahan, 1994).

Missing data. Missing data ranged from 0% to 36% across variables (*Mdn* = 16%). The most frequently missing data were for harsh physical discipline (26% missing at baseline, 36% missing 18 months postbaseline, and 34% missing 36 months postbaseline). Missing data were addressed using full information maximum likelihood estimation under the assumption that the data were missing completely at random or for reasons that could be explained by other variables included in the model (Little & Rubin, 1987). In technical terms, a covariance coverage matrix is created that provides the proportion of available observations for each time point and pairs of time points. This method is a widely accepted method of addressing missing data within an SEM framework while allowing for the inclusion of all available data points (Arbuckle, 1996; Enders, 2001; Raykov, 2005), and in the present study retained all 2,925 participants for the analyses.

Key Variable Correlations

The correlations between all variables in the models are displayed in Table 2. Within-wave correlations between witnessing violence and children's internalizing and externalizing symptoms were consistently small, but significant (*r*s = .09–.17). Within-wave correlations between harsh physical discipline and children's internalizing and externalizing symptoms were small to moderate in magnitude (*r*s = .11–.25). Within-wave correlations between witnessing violence and harsh physical discipline were small, but statistically significant (*r*s = .07–.10)

Externalizing Symptoms

Baseline model. We estimated a baseline LDS model for the repeated measure of externalizing symptoms as assessed at baseline, 18 months postbaseline, and 36 months postbaseline, thereby creating two LDS that represent the change in externalizing symptoms between data collection waves (Figure 1). Alpha was set at .05, and thus all results reported as significant are $p < .05$ or better. The baseline model fit the observed data well, and the model fit was significant, $\chi^2(1) = 23.31$, CFI = 0.99, TLI = 0.95, RMSEA = 0.09. The model-implied mean level of externalizing symptoms decreased significantly from 16.15 to 14.43

externalizing symptoms from baseline to 36 months postbaseline. As displayed in Table 3, results from the model indicated that there was enough variability in how children changed between assessment points (i.e., variance in the difference scores) to justify testing whether the variation in children's latent externalizing change scores could be explained by witnessing violence and/or experiencing harsh physical discipline.

Does exposure to violence predict changes in children's externalizing scores? Next, we built on the baseline LDS model (Figure 2) to examine the effects of witnessing home violence and experiencing harsh physical discipline on children's externalizing symptoms, after controlling for child gender, family income, caregiver psychopathology, and child age (for ease of presentation, these covariates do not appear in the figure, although the parameter estimates appear in Table 3). The model fit the data adequately, and the model fit was significant, $\chi^2(32) = 315.60$, CFI = 0.93, TLI = 0.88, RMSEA = 0.07. Although the TLI has fallen below 0.90, the CFI and RMSEA were still good for a model of this complexity. There was no relationship between witnessing violence and change in externalizing symptoms across assessments ($\beta_1 = 0.04$, $z = 1.02$, *ns*; $\beta_2 = 0.03$, $z = 1.02$, *ns*). However, experiencing harsh physical discipline did predict significant changes in children's externalizing symptoms across assessments ($\beta_1 = 0.12$, $z = 2.95$; $\beta_2 = 0.09$, $z = 2.95$). Although, on average, externalizing problems declined over time, children who experienced relatively high levels of harsh physical discipline showed more gradual declines and, in some cases, increases in externalizing problems from baseline to 36 months postbaseline. This effect remained statistically significant after controlling for child and family risk factors.

We also ran a multiple group model in order to examine whether maltreatment subtype moderated the relationship between exposure to violence (harsh physical discipline or witnessing violence) and changes in externalizing problems. Specifically, we were interested in whether the effects of exposure to violence differed for children who had been physically abused versus children who had experienced

Figure 2. Latent difference score (LDS) model for the relationship between witnessing violence, physical discipline, and externalizing symptoms (*N*= 2,925).

Note. In this model, Δ Score 1 is the LDS representing the change in externalizing symptoms from baseline to 18 months. Δ Score 2 is the LDS representing the change in externalizing symptoms from 18 months to 36 months. The nonindependence of witnessing violence across assessments is represented by the regression of witnessing violence on itself across baseline, 18-month and 36-month assessments. The nonindependence of experiencing physical discipline across assessments is represented by the regression of physical discipline on itself across baseline, 18-month and 36-month assessments. Double-headed arrows represent the variance of latent and observed variables. Although not shown in the model for sake of clarity, the correlation between witnessed violence and harsh physical discipline was small but significant ($r = .06, p < .05$). Parameter estimates in Figure 2 are adjusted for age, gender, caregiver mental health, and income. Parameter estimates for the covariate controls are not included in Figure 2 but are available in Table 3.

$^{**}p < .01$. $^{***}p < .001$.

other forms of abuse. We hypothesized that exposure to violence might evoke a response that either reflected habituation or sensitization processes in youth who had already experienced physical violence. However, the model in which the effects of exposure to violence on children's externalizing symptoms were constrained to be the same for children who were physically abused versus children who were not physically abused was not a significantly worse fit than the model in which the effect of exposure to violence was free to vary across abuse subgroups, $\chi^2(2) = 0.7$, *ns*. Full analyses are available from the authors upon request.

Internalizing Symptoms

Baseline model. We estimated a baseline LDS model for the repeated measure of internalizing symptoms as assessed at baseline, 18 months postbaseline, and 36 months postbaseline, thereby creating two LDS that represent the change in internalizing symptoms between data collection waves (Figure 3). The baseline model fit the observed data adequately and the model fit was significant, $\chi^2(1) = 32.53$, CFI = 0.98, TLI = 0.90, RMSEA = 0.10. The model-implied mean level of internalizing symptoms decreased significantly from 10.41 to 9.32, internalizing symptoms from baseline to 36 months postbaseline. As displayed in Table 4, results from this baseline model indicated that there was enough variability in how children changed between assessment points to justify testing whether the variation in children's latent internalizing change scores could be explained by witnessing violence and/or experiencing harsh physical discipline.

Does exposure to violence predict changes in children's internalizing scores? Next, we built on the baseline LDS model (Figure 4) to examine the effects of witnessing home violence and experiencing harsh physical discipline on children's internalizing

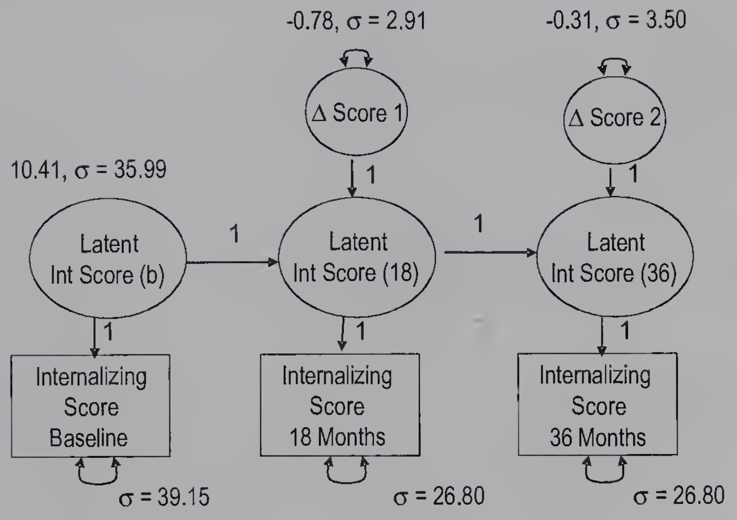

Figure 3. Baseline latent difference score (LDS) model for internalizing symptoms.
Note. In this model, Δ Score 1 is the LDS representing the change in internalizing symptoms from baseline to 18 months. Δ Score 2 is the LDS representing the change in internalizing symptoms from 18 months to 36 months. Double-headed arrows above the LDS represent the variance (σ) of the difference scores. Observed scores (internalizing scores) reflect true scores plus error. Double-headed arrows attached to the observed scores represent the error variance (σ) of the internalizing scores at each assessment.

symptoms, after controlling for child gender, family income, caregiver psychopathology, and child age (for ease of presentation, these covariates do not appear in the figure, although the parameter estimates appear in Table 4). The model fit the data adequately, and the model fit was significant, $\chi^2(32) = 361.60$, CFI = 0.92, TLI = 0.85, RMSEA = 0.07. Although the TLI has fallen below .90, the CFI and RMSEA were still good for a model of this complexity. There was no relationship between harsh physical discipline and change in internalizing symptoms across assessments ($\beta_1 = 0.07$, $z = 1.56$, *ns*; $\beta_2 = 0.06$, $z = 1.56$, *ns*). However, witnessing violence in the home did predict significant changes in children's internalizing symptoms across assessments ($\beta_1 = 0.11$, $z = 2.91$; $\beta_2 = 0.12$, $z = 2.91$). Although, on average, internalizing problems declined over time, children who witnessed relatively high levels of home violence showed more gradual declines and, in some cases, increases in internalizing problems from baseline to 36 months postbaseline. This effect remained statistically significant after controlling for child and family risk factors.

We also ran a multiple group model in order to examine whether maltreatment subtype moderated the relationship between exposure to violence and internalizing problems. Again, we were specifically interested in whether the effects of exposure to violence differed for children who had been physically abused versus children who had not been physically abused. The model in which the effect of exposure to violence on children's internalizing symptoms was constrained to be the same for children who were physically abused versus children who were not physically abused was not a significantly worse fit than the model in which the effect of exposure to violence was free to vary across abuse subgroups, $\chi^2(2) = 3.30$, *ns*. Full analyses are available from the authors upon request.

Discussion

Exposure to violence was associated with changes in children's psychopathology symptoms in this study of children previously reported to CPS. Specifically, harsh physical discipline was associated with

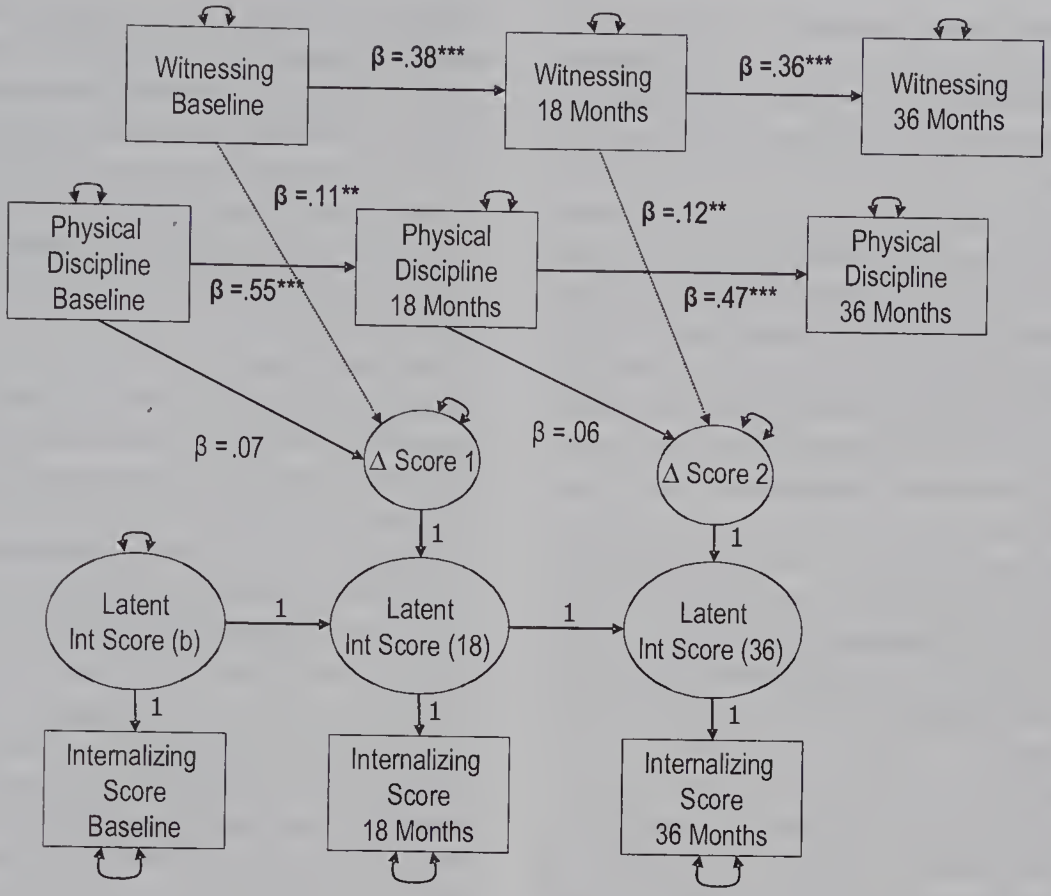

Figure 4. Latent difference score (LDS) model for the relationship between witnessing violence, physical discipline, and internalizing symptoms ($N = 2{,}925$).

Note. In this model, Δ Score 1 is the LDS representing the change in internalizing symptoms from baseline to 18 months. Δ Score 2 is the LDS representing the change in internalizing symptoms from 18 months to 36 months. The nonindependence of witnessing violence across assessments is represented by the regression of witnessing violence on itself across baseline, 18-month and 36-month assessments. The nonindependence of experiencing physical discipline across assessments is represented by the regression of physical discipline on itself across baseline, 18-month and 36-month assessments. Double-headed arrows represent the variance of latent and observed variables. Although not shown in the model for sake of clarity, the correlation between witnessed violence and harsh physical discipline was small but significant ($r = .06$, $p < .05$). Parameter estimates in Figure 2 are adjusted for age, gender, caregiver mental health, and income. Parameter estimates for the covariate controls are not included in Figure 4 but are available in Table 4.
$^{**}p < .01$. $^{***}p < .001$.

deviations from the normative sample trajectory of declining externalizing symptoms and witnessing home violence was associated with deviations from the normative sample trajectory of declining internalizing symptoms. These effects of family violence were significant even controlling for two potential confounds—family income and caregiver mental health—and after controlling for the child's gender and age.

This study had several methodological strengths. First, the sample size was large ($N = 2{,}925$) and nationally representative of children involved with CPS in the United States. Second, whereas current caregivers reported on their children's externalizing and internalizing symptoms, the children themselves reported on the levels of violence they witnessed in the home. Past studies suggest that caregivers significantly underestimate the amount of domestic violence to which their children are exposed (Jaffe, Wolfe, & Wilson, 1990; O'Brien, John, Margolin, & Erel, 1997). Third, we utilized an SEM approach (LDS modeling) that allowed us to examine the association between witnessing violence, harsh physical discipline, and child psychopathology after controlling for normative developmental changes in children's externalizing and internalizing symptoms over a 36-month period as well as a number of potential confounds. The modeling technique also allowed us to account for the nonindependence of exposure to violence over time. Many past studies in this field have lacked either longitudinal data or sufficient power to take into account children's normative symptom changes and to adequately control for important confounds. Furthermore, because violent discipline tactics and domestic violence witnessed by children frequently co-occur, it is important to attempt to tease apart the effects of each type of violence so as to inform future studies and interventions. Our modeling technique allowed us to examine these questions.

Our findings were largely consistent with the extant literature showing that violence exposure is associated with psychopathology symptoms in children. Additionally, we ruled out three alternative explanations for why harsh physical discipline and witnessing violence were associated with child psychopathology.

First, in light of the extensive body of literature showing that mental health problems run in families (e.g., Kendall, 2000), it is not surprising that in our sample, caregivers with poor mental health were raising children who had elevated levels of externalizing and internalizing symptoms. However, exposure to violence was still predictive of children's psychopathology symptom changes even after controlling for caregiver mental health. Thus, we can conclude that our results are not simply reflective of a spurious association between family violence and child psychopathology generated by caregiver mental health problems or by transmission of a genetic vulnerability for mental health problems from parents to children.

Second, multiple studies have shown that poverty is associated with elevated rates of child psychopathology (Bradley & Corwyn, 2002; Brooks-Gunn & Duncan, 1997; Costello et al., 2003; McLoyd, 1997). In addition, studies suggest that low-socioeconomic status (SES) parents are more likely than high-SES parents to engage in harsh or neglectful parenting styles, which are associated with more childhood problem behaviors (e.g., Bradley & Corwyn, 2002). However, harsh physical discipline was uniquely associated with externalizing symptoms and witnessing violence was uniquely associated with internalizing symptoms even controlling for family income.

Third, it is conceivable that changes in children's symptoms merely reflect the passage of time and normative trajectories. However, in our models, we controlled for children's expected symptom trajectories and showed that exposure to violence predicted deviations from these trajectories.

Implications for Research and Theory

We suggest that more research is needed to better understand why family violence increases risk for children's mental health problems. For example, although NSCAW children reported on the violent events they witnessed, they were not asked how they encoded or interpreted the events (or indeed how they encoded physical punishment). Upon reviewing the literature on children who witness domestic violence, Black and Newman (1996) concluded that researchers should give more consideration to the ways in which children cognitively interpret the violent events they witness, and Crockenburg and Forgays (1996) found that children's negative emotional reactions to their fathers during marital arguments independently predicted children's behavioral adjustment. Future studies might look more closely at how children who have previously been exposed to violence encode violent events they witness and the ways in which their parents discipline them in order to help better understand the long-term effects of family violence.

Children who have been exposed to violence severe enough to bring them to the attention of CPS, such as the children in this sample, might be particularly vulnerable to encoding the incidents they witness or experience themselves in a way that contributes to an internal representation of the world as extremely violent, unsafe, and unpredictable and, consequently, might have stronger and more negative emotional reactions to violence and conflict. Several studies have shown that children's histories, including their past exposure to parental conflict, influence how and how much witnessing marital conflict affects them (e.g., Cummings, Vogel, Cummings, & El-Sheikh, 1989; Davies, Myers, Cummings, & Heindel, 1999). Specifically, children who have been exposed to marital conflict more frequently in the past have more negative emotional reactions to new incidences of interparental conflicts (Davies & Cummings, 1998). If children who have already been victims of maltreatment encode adult domestic violence as especially threatening, this may increase their vulnerability to internalizing and externalizing problems. Pollak's work with physically abused children, for example, suggests that abused children display increased anticipatory monitoring in response to angry interpersonal situations in the environment and display a deficit in their ability to regulate their arousal (Pollak, Vardi, Bechner, & Curtin, 2005).

There are two aspects of the results that should be examined further in future studies. First, physical abuse did not emerge as a significant moderator of the relationship between family violence and children's internalizing and externalizing problems in these analyses. However, the relationship between family violence and other types of psychopathology (or specific symptoms of internalizing and externalizing problems) may indeed depend on the type of abuse the child experienced. Second, experiencing harsh physical discipline was associated with changes in externalizing symptoms, whereas witnessing violence was associated with changes in internalizing symptoms. As reviewed above, other studies have demonstrated that both forms of family violence are associated with both internalizing and externalizing problems. Thus, our findings will need to be replicated in other samples before we can conclude with certainty that different types of family violence have specific effects on different types of child problem behaviors. To the extent that our finding is real, however, one possibility is that the different cognitive meanings these two forms of violence have for children lead to different manifestations of distress.

Finally, other research conducted with the NSCAW sample (Jaffee & Gallop, 2007) and with other samples (Cicchetti & Rogosch, 1997) has found that formerly abused children who are "free" of significant mental health problems at one point in time rarely maintain good mental health over time. Our study suggests that one reason may be that children with histories of abuse are often reexposed to various forms of violence that predict the recurrence of mental health problems. Again, more research is needed in this area.

Implications for Practice and Policy

Victims of abuse and neglect are at elevated risk of witnessing and experiencing other forms of family violence. The results of this study suggest that intervention efforts to reduce rates of mental health problems in child victims of maltreatment must focus not only on protecting children from revictimization but must also work to decrease even nonabusive forms of physical discipline and the amount of adult domestic violence children witness in their homes. Intervention efforts might help parents manage relationship conflict or, at the very least, educate parents about the importance of buffering children from exposure to conflict.

Past research on children's emotional responses to witnessing marital conflict suggests that children are less distressed by nonviolent conflict when conflicts are resolved with a compromise or an apology (Cummings, Ballard, El-Sheikh, & Lake, 1991). Future studies could explore whether this finding holds for children who witness *violent* conflict in the home. The impact of various resolution strategies might differ for children who witness violent forms of conflict, in that children who witness a continuous cycle of domestic violence and resolution of violence (such as an abusive father who breaks down into tears and apologizes to the child's mother but then abuses her again the next week) might actually normalize violence and be more prone to future problems. Given past research suggesting that children who witness domestic violence are at risk of encoding violence as an acceptable behavior in relationships (Black & Newman, 1996), resolution-improving interventions might emphasize not only that the behavior was unacceptable but also model for children more appropriate conflict-resolution strategies and disciplinary techniques.

In sum, our findings suggest that reducing the amount of violence that children witness in the home and the frequency with which their parents use harsh physical discipline could be important foci of effective family therapy interventions and prevention programs for this vulnerable population. Preventing abuse from reoccurring may not be enough to divert children from the maladaptive trajectories on which their past abuse and home environments contributed to placing them in the first place.

Limitations

First, although harsh physical discipline and witnessing violence were significant and unique predictors of psychopathology symptoms, the zero-order correlations among these variables were modest. Second, although reliability and validity statistics for the short-form health survey (from which we created our caregiver mental health variable) were good, the measure is a broad and general measure of mental health. It does not ask questions about specific mental illnesses but rather asks more about daily impairment due to emotional problems. Third, it is possible that some parents underreported their use of violent disciplinary techniques or children's problems, given that they had already been brought to the attention of CPS. Although efforts were made to minimize this possibility by administering questions about physical discipline via an audio computer-assisted interview and interviewers were thus unaware of parents' responses, Tourangeau and Yan's (2007) meta-analysis found that computer administration did not lead to significantly increased reporting of sensitive information by research participants and, indeed, rates of missing data were higher for this variable than for others.

Fourth, although we included a number of variables in the LDS models that might have accounted for the association between children's experiences of family violence and their problem behaviors, it is possible that important confounds were not assessed (e.g., measures of neighborhood violence). Moreover, although we attempted to rule out the possibility that poverty accounted for the association between family violence and child psychopathology, it is possible that there was insufficient variability in income in this high-risk sample to adequately test this hypothesis. Fifth, although youth reported on witnessed violence in the home, caregivers reported on children's experiences of harsh physical discipline as well as child psychopathology symptoms, introducing shared informant variance. Sixth, although our models tested whether higher levels of violence predicted changes in psychopathology symptoms, we did not explicitly test whether changes in harsh discipline and witnessed violence predicted changes in psychopathology. Future research should examine this question, especially research intervention designs that alter parenting practices.

Children continue to be victimized by and exposed to domestic violence at alarming rates. In all likelihood, these children are at increased risk of psychopathology symptoms not only because they have been maltreated or exposed to violence but also because of their family's poverty status, the neighborhood violence they witness, the poor schools they attend, and the inadequacy of their housing. Thus, studies that explore how and why specific aspects of these early childhood environments affect children's mental health are important foundational work that will allow for the development of more efficacious, cost-effective, and targeted interventions. Studies that test alternative hypotheses about links between family violence and child psychopathology help researchers develop more specific hypotheses about mechanisms that link early childhood stressors to child socioemotional development.

Limitations in 4-Year-Old Children's Sensitivity to the Spacing Among Facial Features

Catherine J. Mondloch and Kendra Thomson
Brock University

Four-year-olds' sensitivity to differences among faces in the spacing of features was tested under 4 task conditions: judging distinctiveness when the external contour was visible and when it was occluded, simultaneous match-to-sample, and recognizing the face of a friend. In each task, the foil differed only in the spacing of features, and spacing alterations were within normal limits. Children performed at chance levels in all but 1 task—match-to-sample, and in that task, only 10 of 18 children were correct on more than 50% of the trials. Sensitivity to the spacing of facial features in identity and distinctiveness tasks is very weak at 4 years of age—at least when the changes do not exceed ±2.5 *SD* of normal variability.

Adults are experts at recognizing facial identity: They can recognize thousands of faces, including, at least for a short time, ones they encounter briefly in the course of a laboratory experiment (see Bruce & Young, 1998, for a review). Adults use multiple cues to recognize the identity of individual faces, two of which have been studied extensively in children: the shape of individual features (e.g., eyes, mouth, and chin: *featural processing*) and the spacing of the facial features (e.g., the distance between the eyes, a type of configural processing called *second-order relational processing*; for a review, see Maurer, Le Grand, & Mondloch, 2002). Despite the early emergence of some face-processing skills, adult-like expertise is not achieved until some time during adolescence: Even in matching tasks, which eliminate memory demands, performance improves dramatically between 4 and 11 years of age (Bruce et al., 2000; see also De Sonneville et al., 2002).

Two lines of evidence suggest that children's poor performance on face recognition tasks can be attributed in part to immature sensitivity to second-order relations. First, children perform like adults on identity tasks that tap sensitivity to the appearance of individual features. For example, when asked to make same/different judgments about pairs of faces that differ only in the shape of the external contour, 6-year-olds are as accurate as adults. They are nearly like adults when making same/different judgments about pairs of faces that differ only in the shape of internal features (eyes and mouth), with no statistical difference by 10 years of age (Mondloch, Le Grand, & Maurer, 2002; see also Freire & Lee, 2001). Second, children aged 6–14 years make significantly more errors than adults when asked to make same/different judgments about pairs of faces that differ only in the spacing of features (Freire & Lee, 2001; Mondloch, Dobson, Parsons, & Maurer, 2004; Mondloch et al., 2002, 2003).

There is general consensus that children are less sensitive than adults to the spacing among facial features (but see Gilchrist & McKone, 2003; Pellicano, Rhodes, & Peters, 2006), but there is debate as to when this sensitivity first emerges. Although less accurate than adults, even 6-year-olds' accuracy is above chance levels in making same/different judgments about upright faces differing only in the spacing of their features ($M = 0.69$ correct vs. 0.82 correct for adults tested with the same task; Mondloch et al., 2002). In addition, like adults, 7-year-old children remember distinctive faces better than typical faces, regardless of whether the faces are made distinctive by manipulating features (e.g., bushy eyebrows) or their spacing (e.g., mouth up; Gilchrist & McKone, 2003).

To investigate when sensitivity to the spacing among facial features first emerges, Mondloch, Leis, and Maurer (2006) asked 4-year-old children to recognize each of three faces when paired with a foil that

differed from the target in one of three ways: the shape of the external contour, the appearance of individual features, or the spacing among features. Four-year-olds were familiarized with two of the target faces over a 2-week period by providing them with a storybook depicting two children on a visit to the farm. To encourage attention to second-order relations, Mondloch et al. varied the appearance of facial features by presenting the faces of the two children in the storybook from different points of view and with a variety of emotional expressions. The third target face was the child's own. Recognition was tested in the context of a computerized game in which 4-year-olds used a "magic wand" to put children on a bus or train during a trip to the zoo. Four-year-olds made no errors on control trials in which the foil was the face of another child or in which the foil had a different external contour; they performed above chance levels when the foil differed in the shape and color of the eyes and mouth. In contrast, 4-year-olds performed at chance levels when the foil differed from the target only in the spacing of facial features, both when tested with the two target faces from the storybook and when tested with their own face. Mondloch et al. concluded that sensitivity to second-order relations emerges after 4 years of age—at least for facial identity tasks when the spacing of features remains within normal limits

In the same year that Mondloch et al. (2006) published their manuscript, two other studies reported that 4-year-old children are sensitive to the spacing of facial features. Pellicano et al. (2006) tested children's sensitivity to the spacing of facial features using the *whole/part* paradigm. The *whole/part effect* is a measure of holistic processing (Tanaka & Farah, 1993) and refers to the finding that adults and children as young as 4 years of age recognize the features from an individual's face more easily in the context of the whole face (e.g., Larry's nose in Larry's face) than in isolation (Pellicano & Rhodes, 2003; Tanaka, Kay, Grinnell, Stansfield, & Szechter, 1998). The usual interpretation of the whole/part paradigm is that poor performance in the isolated features condition indicates that faces are processed holistically (i.e., as a gestalt) and that characteristics of individual features are encoded in the context of this gestalt representation (Tanaka & Farah, 2003). Disrupting holistic processing by presenting features in isolation impairs recognition of features, as does altering the gestalt by changing second-order relations (Tanaka & Sengo, 1997). Pellicano et al. showed that altering the spacing of facial features in one part of a face also impairs the ability of 4-year-olds to recognize facial features in the whole condition.

McKone and Boyer (2006) reported that 4-year-olds are sensitive to differences in the spacing of facial features when asked to judge which of two faces is more distinct. They manipulated facial distinctiveness by altering the appearance of individual features (e.g., by making the eyebrows bushy) or by altering the spacing among features. Based on adult ratings of the original and distorted faces viewed one at a time, McKone and Boyer created pairs of faces in which differences in distinctiveness between the original face and its altered version were large, medium, or small. Adults and 4-year-olds were then asked to indicate which member of each pair was more distinctive; adults' performance was above chance for all pairings, and 4-year-olds' performance was above chance when differences in distinctiveness were either large or medium.

The purpose of the present set of studies was to resolve these discrepant findings. It may be that sensitivity to differences among faces in the spacing of facial features emerges at different rates for recognizing a face's identity than for judging distinctiveness. In the current series of studies, we measured 4-year-olds' sensitivity to the spacing of facial features under several task conditions—when judging distinctiveness, in a simultaneous match-to-sample task, and when recognizing the faces of friends from a day care. In all these studies, the spacing changes were identical to those used by Mondloch et al. (2006). This allowed us to assess whether 4-year-olds would show sensitivity to those spacing changes under different task conditions. Furthermore, we made each task child friendly: The number of trials was minimized (four test trials plus eight control trials), and children were presented with a "game" in which they used a magic wand to put faces on a bus or put twins into a "twin clubhouse."

Experiment 1a

Previously, we reported that 4-year-olds were not able to recognize either faces from a storybook or their own face when targets were paired with foils that differed only in the spacing of facial features (Mondloch et al., 2006). This result is in contrast to that of McKone and Boyer (2006) who reported that 4-year-olds were able to select the more distinctive of two faces that differed in the spacing of features, as long as the differences in distinctiveness were either large or medium according to adult judgments. In Experiment 1a, we showed children four pairs of faces that differed in the spacing of features and asked them to use a magic wand to put the more unusual child on an "unusual" bus. Each of the spatially altered faces had been rated as more distinctive than its original version when adults viewed three versions of each of 26 faces sequentially (Mondloch et al., 2006); in that study, 4-year-olds performed at chance levels in an identity task. If the spacing of facial features influences children's judgments of distinctiveness by 4 years of age, they should select the more distinctive version of each face (Mondloch et al., 2006). We also tested a group of adults in the current study using the method designed for children. We expected that adults would perform without error, thus validating our stimulus set.

Method

Participants

Eighteen 4-year-old children (9 females; mean age = 4.43 years, range = 4.0–4.9 years) participated in this study. Twelve adults (mean age = 19.9 years, range = 19.0–23.6) with normal or corrected-to-normal vision served as a control group. All participants were Caucasian. Children in all the experiments were recruited from a database of children whose parents had volunteered for participation or from local day cares whose parents had provided informed consent. Adult participants received course credit.

Materials

Test stimuli. On each of the four test trials, we presented an original (i.e., unaltered) face paired with a foil that differed only in the spacing of internal features. We selected four face pairs from Experiment 1 of Mondloch et al. (2006). We used the original faces of the two storybook characters plus the faces from two of the participants in that study. Adults had previously rated each of these faces on a distinctiveness scale (Mondloch et al., 2006, Experiment 2b) and reported that the spatially altered versions were more distinct than the original faces (mean difference = 1.66, *SE* = 0.22). In this and all subsequent studies, the faces were close to life size: The distance between the chin and the hairline was 130 mm. Based on anthropomorphic norms (Farkas, 1994), we had moved the eyes up/down 21 pixels (where 1 pixel = 0.353 mm; 1.3 *SD*; 0.71° from the testing distance of 60 cm) or closer together or farther apart 14 pixels (2.8 *SD*; 0.47° from 60 cm) and we moved the mouth up/down 7 pixels (0.8 *SD*; 0.24° from 60 cm). Thus, these spacing changes covered most of the natural variability in the real world and consequently remained within normal limits. Two of the test faces had the eyes and mouth moved up and two had the eyes and mouth moved down. Figure 1a provides an example.

Criterion stimuli. Two sets of criterion stimuli were used to ensure that the 4-year-olds understood the task and that they continued to "play the game" throughout the procedure. One set consisted of four animals (e.g., a horse, a squirrel) paired with a "weird" version of that same animal (e.g., a horse with stripes, a squirrel with pigs' ears; Figure 1b). The other set consisted of grayscale photographs of adult Caucasian women paired with a spatially altered version in which the spacing of facial features was outside normal limits. Adults and 8-year-olds rate these spatially altered versions as grotesque (Mondloch et al., 2004), and unpublished data of Mondloch and Maurer (2003) show that 4-year-olds find these faces weird (Figure 1c).

Procedure

The child sat 60 cm away from a 58-cm computer screen. We began by presenting a picture of two buses, one of which was a typical school bus and one of which was weird. The experimenter said, "Look at these two buses. Do you think that one of these buses is a bit strange or unusual or weird? Which one? Why do you think that bus is weird? Good job! Now we are going to go for a ride with this bus and help some people and animals get back to their town. Do you think you can help me? Great!" Each trial consisted of two photos of animals, children's faces, or adult female faces. The experimenter asked, "Do you think one of these (animals, females, or children) is a bit strange, unusual, weird, or might stick out to you if you saw them on the playground? Good, now wave your magic wand to put the weird (animal, female, or child) on the weird bus!" After the child waved their magic wand over one of the pictures, a small picture of that stimulus appeared on the bus. The order of the trials was such that all participants received four criterion trials (two animals, two adult female faces), followed by two test trials (children's faces). Participants then received two more criterion trials (animals), followed by the remaining two test trials. We ended with two final criterion trials (adult female faces) to ensure that children were still "playing the game." An alternate version of the task was created so that the left–right positions of the stimuli were reversed. To ensure that the experimenter was blind to the location of the more distinctive stimulus, another laboratory member opened one of the two files on the computer for the experimenter. The experimenter viewed the stimuli on a laptop computer on which the pictures were occluded. This

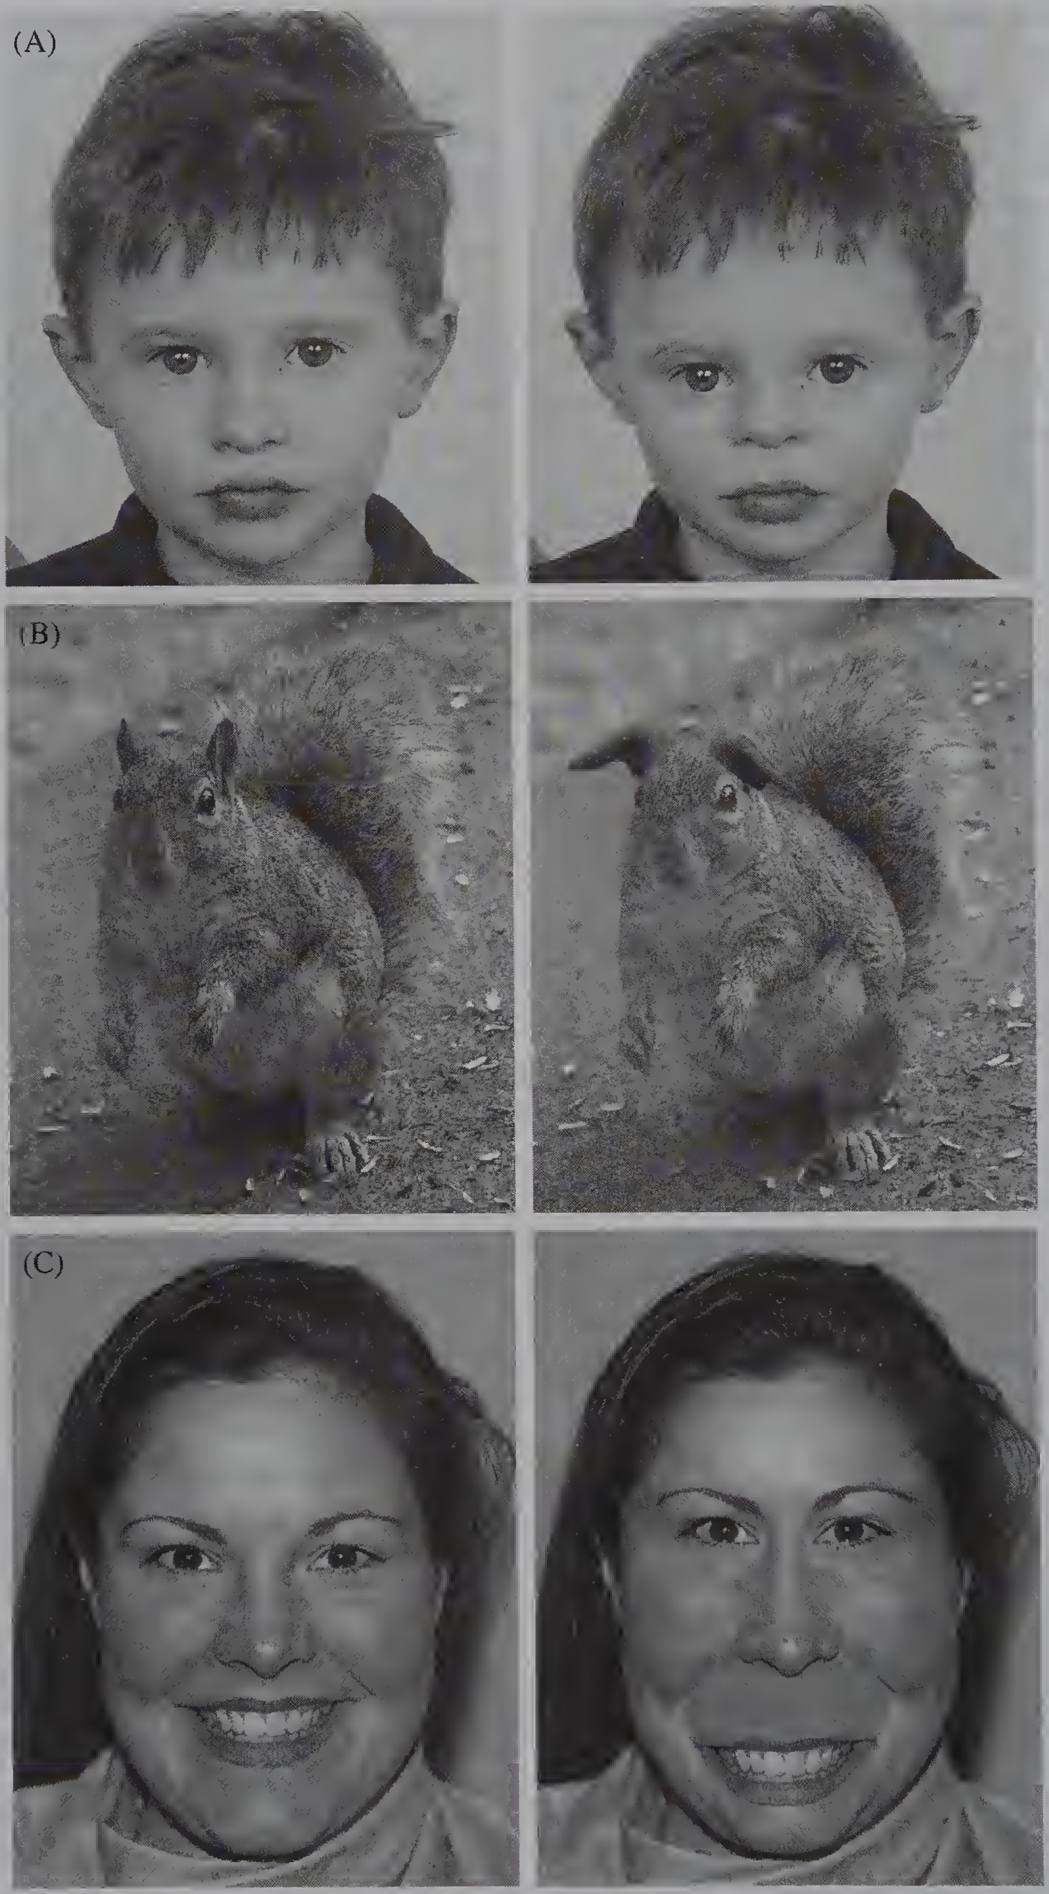

Figure 1. Examples of stimuli used during (a) test trials, (b) criterion trials in which animals were presented, and (c) criterion trials in which adult faces were presented. In each case, the original picture is shown on the left and the altered (i.e., distinctive) picture is shown on the right. The spacing changes made to adult faces were outside normal limits; spacing changes made to children's faces were within normal limits.

protocol was approved by the Research Ethics Board at Brock University.

Results and Discussion

Children made almost no errors when asked to find the more distinctive animal, mean correct (on four trials) = 3.90, $t(17) = 35.0$, $p < .001$, and when asked to find the more distinctive adult face, mean correct = 3.70, $t(17) = 14.6$, $p < .001$ (all tests were one-tailed). Children performed at chance levels, mean correct = 1.90, on trials in which the original version of a child's face was paired with its spatially altered version and the spacing changes were within normal limits. Only 7 of the 18 children tested were correct on at least three of the four test trials. A control group of 12 adults (7 females) performed at 100% accuracy on all trial types, confirming that the spatially altered faces are easily detected as the most distinctive by adults. These data suggest that 4-year-olds are not able to use information about the spacing of facial features to determine which of two faces is more distinctive when the spacing changes are within normal limits. This is in contrast to the findings of McKone and Boyer (2006) who reported above-chance performance in 4-year-olds—at least when differences in distinctiveness were large or medium in size. We note, however, that McKone and Boyer occluded the external contour of their face stimuli, whereas the hair was visible in our stimuli, albeit identical within each stimulus pair. Several studies have demonstrated that the external contour is a salient stimulus to young children (Campbell & Tuck, 1995; Campbell, Walker, & Baron-Cohen, 1995; Mondloch et al., 2006); to see whether the presence of hair interfered with children's performance, we replicated the procedure of Experiment 1a, but occluded the hair.

Experiment 1b

Method

Participants

Eighteen 4-year-old children (5 females; mean age = 4.38 years, range = 4.0–4.7 years) participated in this study. All participants were Caucasian. Experiment 1b was identical to Experiment 1a, with one exception: The hair was occluded on children's faces (participants were told that the children were peeking through windows).

Results and Discussion

No child made an error on criterion trials, but performance was at chance levels when children were asked to find the more distinctive face on test trials, mean correct = 2.20, $t(17) = 0.62$, $p > .2$. Only 6 of the 18 participants were correct on at least three of the four test trials. These data confirm that 4-year-olds do not attend to the spacing among facial features per se when making distinctiveness judgments.

At first glance, it appears that our results contradict those of McKone and Boyer (2006) who reported that 4-year-old children judge spatially altered faces as more distinctive than their original versions. However, in their study, 4-year-olds were much less accurate than adults even when the spacing changes were large (mean correct = 0.90 vs. 0.62 for adults and children, respectively). When differences in distinctiveness were small, 4-year-olds did not perform above chance levels, whereas adults were correct on approximately 75% of the trials. Thus, even in McKone and Boyer's study, 4-year-olds' sensitivity to the spacing of facial features was much weaker than that of adults and was most reliable when differences in distinctiveness were large according to adult ratings. Likewise, in the current study, 4-year-olds were able to use information about the spacing of facial features when the spacing changes were large and outside normal limits (i.e., when making distinctiveness judgments about the adult faces). The high level of accuracy shown for adult faces with large spatial distortions (12 children correct on four of four trials; 6 children correct on three of four trials) in contrast to chance performance for children's faces with spatial distortions that contrast more or less average spacing with the edge of natural limits suggests that 4-year-old children are sensitive to differences among faces in the spacing of features but only when those differences are large. One potential limitation of our study is that two training trials in which differences in distinctiveness were large preceded the first two test trials. We did this in order to familiarize children with the task. Although one possibility is that the spacing changes made to the children's faces were harder to detect after viewing the large spacing changes in adult faces, we reasoned that viewing the large spacing may direct 4-year-olds' attention to this cue to distinctiveness. Nonetheless, we note that this may have made the task more difficult for the children.

Experiment 2

In Experiment 2, we simplified the task for 4-year-old children by presenting them with a simultaneous match-to-sample task. On each of four test trials, they were shown a child's face (either original or spatially altered) and then shown a pair of faces, one of which was identical to the target and one of which differed only in the spacing of features. Children were asked which member of the face pair matched the target; they then placed the "twins" in a "twin clubhouse." This task involved no memory demands and allowed the child to compare the target face to two test faces with no time restrictions. We also included criterion trials in which children were presented with sets of adult faces and animals from Experiment 1.

Method

Participants and Materials

Eighteen 4-year-old children (8 females; mean age = 4.44 years, range = 4.0–4.9 years) participated in this study. All participants were Caucasian. The test stimuli were identical to those used in Experiment 1a; they were printed and laminated to allow the child to handle the faces. We created a twin clubhouse into which children were invited to place identical pictures.

Procedure

Each participant sat at a table with the stack of cards containing stimulus pairs in front of him or her. The experimenter sat next to the participant with an additional stack of individual stimuli. The twin clubhouse was placed directly in front of the participants. First, participants were shown a drawing of three bears, two of which were identical and one that was only slightly different. The experimenter said, "Do you know what twins are? Can you pick out the twins from these three bears?" If participants did not understand the differences between the bears, the experimenter explained, "Twins are people or animals that look exactly the same." Next, the experimenter told participants, "Today I have a special job for you! You are going to be a 'twin detective'! Some kids, animals and adults are starting a special 'twin clubhouse' where only twins can go. Can you help me find twins to put in the twin clubhouse? Great! First I am going to flip over a card with an animal (or face) on it and then you can flip your card that will have two pictures of animals (or faces) on it. Your job is to pick the animal (or face) from your card that is exactly like the animal (or face) on my card (the animal's/person's twin)! Then we can put the twin animals/people in the twin clubhouse. Remember to look carefully at both of the pictures on your card!"

Results and Discussion

Children made no errors on the animal criterion trials, and only 3 children made a single error on the criterion trials in which we presented adult faces. Their performance was above chance, $M = 2.40$, $t(17) = 1.80$, $p < .05$, when tested with children's faces, though only 10 of the 18 participants were correct on at least three of the four test trials. These data suggest that the visual system of 4-year-old children is able to detect differences in the spacing of facial features, a finding that is consistent with report by Pellicano et al. (2006) of sensitivity to the spacing of features in the whole/part paradigm. Four-year-olds showed sensitivity to the spacing of facial features in our match-to-sample task in which they were required only to match facial identity; this is in contrast to when they were asked to recognize a face from memory (Mondloch et al., 2006) or to decide which of two faces was distinctive (Experiment 1). Nonetheless 8 of the 18 children tested were not correct on more than 50% of the trials, suggesting that 4-year-olds' sensitivity to the spacing of facial features is weak even in a matching task. Based on this, it is unlikely that they use the spacing of facial features to recognize faces in the real world.

Nonetheless, we may have underestimated children's sensitivity to second-order relations by testing them with unfamiliar faces. Carver et al. (2003) reported an effect of familiarity on the Nc component of the event-related potential waveform between 18 and 24 months of age; this raises the possibility that children may process highly familiar faces differently from unfamiliar faces. Mondloch et al. (2006) tested 4-year-olds with familiarized faces from a storybook and with their own faces. We reasoned, however, that 4-year-olds do not see their own face as often as that of people with whom they interact on a daily basis and they do not see their own face from a variety of perspectives and displaying a range of facial expressions. In Experiment 3, we tested the hypothesis that 4-year-olds may be sensitive to the spacing of facial features when asked to identify the "real" picture of a highly familiar face—that of a friend from their day care. To do so, we replicated the original method of Mondloch et al. (2006) but replaced pictures of the storybook character and the participant's own face with the faces of three friends from the participant's day care.

Experiment 3

Method

Participants

Eighteen 4-year-old children (6 females; mean age = 4.25 years, range = 4.0–4.9 years) participated in this study. All participants were Caucasian. All participants attended a day care and were highly familiar with the faces of children who served as models. Two additional children were tested but excluded from the analyses. One child was able to identify only two of his three friends when shown the initial array of stimuli, and the other was incorrect on all three contour trials. This poor performance is very atypical (Mondloch et al., 2006); therefore, we excluded these children to avoid underestimating 4-year-olds' sensitivity to the spacing of features.

Stimuli

For each participant, a day-care worker identified three children with whom the participant was highly familiar; these children served as models. After obtaining informed parental consent, we took three pictures of each model's face. We then created new versions of each of these pictures. On contour trials, we presented one original version paired with a foil in which we combined the external contour (hair, ears, and chin) of a different child with the internal features and the clothing of the original image. On test trials, we presented an original photograph paired with a spatially altered version. These spatial alterations were identical to those used by Mondloch et al. (2006). On half of the trials, the eyes and mouth were moved either up or down (as in Experiments 1 and 2); on the remaining trials, the eyes were moved 14 pixels closer together and the mouth was moved down 7 pixels or the eyes were moved 14 pixels farther apart and the mouth was moved up 7 pixels. A different original picture was presented on each spacing trial to ensure that participants were recognizing a face, rather than a particular photograph. On control trials, we presented one of the original pictures of the model paired with a picture of another 4-year-old child with whom the participant was not familiar.

Procedure

The child sat 60 cm away from a 58-cm computer screen; during the test, the experimenter faced the child so as to be blind as to on which side of the monitor the "correct" face was presented. We began by presenting an array of six pictures, each of which depicted a 4-year-old child and three of which were friends of the participant. The participant was asked to identify their three friends.

On the first three test trials, the child was shown one of the original faces paired with a face with the same internal features but a different external contour. The background picture consisted of a school bus. The child was told, "Today we are going to pretend that some of your friends are going on a trip to the zoo! But the bus driver doesn't know what all the kids in the class look like, so maybe you can help him out. Here is a magic wand and when you wave the wand the children will get on the bus." Two faces appeared on the face at this time. "Look! It's 'Sam'! And there's another boy who looks a little bit like Sam. Can you wave the magic wand over the real picture of Sam to put him on the bus?" After the child pointed the magic wand to the face he or she thought was Sam's, a new display appeared that consisted of the interior of the bus and a small picture of Sam's face. On this and every subsequent trial, the correct response was placed on the bus (or train). Two additional contour trials followed in which the child was asked to help the bus driver by pointing to their two remaining friends. The purpose of these trials was to illustrate to the child that the members of each face pair would be quite similar, but that only one would be the real person.

The child was then shown a series of four animal pictures (e.g., a monkey, an elephant) and the experimenter continued the story about the trip to the zoo. Then, the game continued: "Oh look, there is a train ride. The kids want to go on the train ride at the zoo, but the conductor doesn't know what the kids look like. Maybe you can help him out. But, it is going to be harder now. Just for today, Sam has a brother who looks a lot like him so it's going to be more difficult to tell them apart so look very carefully." Two faces were then presented on the screen; the faces differed only in the spacing of the facial features. "Here's Sam and Sam's brother. They look a lot alike, but only one of them is really Sam. Can you wave your magic wand at Sam to put him on the train?" When the child waved the magic wand, the experimenter presented a new picture that consisted of a picture of the train overlaid with a small picture of Sam's face. Two additional trials followed in which different friend's faces were presented. The child was then told that it was time for the children to go home but that the bus driver was sad because he could not remember what the children in the class looked like. A second set of spacing trials then ensued, one for each of the three original faces.

To ensure that the child was still attentive at the end of the procedure, three control trials were included. The child was told, "So now the bus takes them all the way back to school. At school, their mommies and daddies are waiting to pick them up. Can you help Sam's mom pick out Sam?" Two faces were presented side-by-side on the screen, but this time, Sam was presented next to a completely different boy. The background consisted of a cartoon version of a car.

After the child pointed to the face he or she thought belonged to Sam, Sam appeared in the passenger side of the car. The same test was then repeated for the other two friends. Any child who could not correctly identify these faces would have been excluded from the study. However, not one child made an error.

For each participant, we created two versions of the test in which the positions of the faces were reversed left to right. We then asked a laboratory member other than the experimenter to randomly open one of the two files to ensure that the experimenter was unaware of on which side the target face was presented.

Results and Discussion

One child made a single error on the contour trials, and no child made an error on control trials. In contrast, 4-year-olds performed at chance levels on the six spacing trials, $M = 3.39$, $t(17) = 1.13$, $p > .10$. Nine of the 18 participants were correct on at least four of the six test trials. Accuracy on the three trials in which the eyes were moved up and down ($M = 1.67$) did not differ from accuracy in which the eyes were moved horizontally, $M = 1.72$, $t(17) = 0.164$, $p > .50$. These results suggest that in previous studies, we had not underestimated 4-year-olds' sensitivity to the spacing among facial features by testing them with unfamiliar or familiarized faces. Even when tested with the faces of children with whom they interact on a daily basis, 4-year-old children do not use differences in the spacing of facial features for face recognition.

General Discussion

This set of studies indicates that 4-year-old children are not sensitive to small differences among faces in the spacing of facial features. They did not select spatially altered faces as more distinctive than the unaltered versions (Experiments 1a and 1b), and they did not select the unaltered versions as the real picture of their friends (Experiment 3). Across these three tasks, no more than half of the children performed better than a chance level of 50%. Their performance was above chance in the simultaneous match-to-sample task (Experiment 2), but only 10 of the 18 children were correct on more than 50% of the trials. Poor performance on these tasks cannot be attributed to 4-year-olds not understanding task instructions; their performance was almost errorless on control trials in which they were asked to select the more distinctive animal or adult female face in which the spacing changes were large and outside normal limits (Experiments 1a and 1b) and when asked to match the identity of these stimuli (Experiment 2). Similarly, only one child made a single error when asked to find the real picture of a friend's face when the foil differed in the appearance of the external contour. Poor performance is also unlikely due to the limited number of test trials. Our decision to include four test trials (plus eight control trials) in Experiments 1 and 2 was based on extensive pilot work showing that increasing the number of trials on a difficult task results in several children failing to complete the procedure and in random performance on control trials. A trial-by-trial analysis reveals no consistent improvement across trials. Across the first three studies, 27 of 54 children were correct on the first test trial and 31 of 54 children were correct on the last test trial. Rather, these results suggest that 4-year-old children are not sensitive to differences among faces in the spacing of facial features, at least when the spacing of features does not exceed ±2.5 *SD* of normal variability.

The nature of our spacing changes should have facilitated 4-year-olds' ability to use second-order relations in each task. In our distinctiveness tasks and in the match-to-sample task, we always moved the eyes vertically. This decision was based on adult ratings of distinctiveness from a previous study (Mondloch et al., 2006). Goffaux and Rossion (2007) reported that inversion disrupts the ability to discriminate faces in which features have been moved vertically more than the ability to discriminate faces in which features have been moved horizontally or in which the appearance of individual features has been altered. They suggest, "It may be that vertical relations are more significant for upright face discrimination than horizontal relations" (p. 1001). This is consistent with evidence from the composite face effect of stronger perceptual integration across the top and bottom halves of faces than across the two sides (Hole, 1994). Thus, the use of vertical movements should have made this task easier for children. In the friends study (Experiment 3), we moved the eyes vertically in half of the trials and horizontally in the other half. When we moved the eyes farther apart, the mouth was moved up; when we moved the eyes closer together, the mouth was moved down. These combinations of movement should have maximally disrupted the aspect ratio of the triangular relations in the original faces (Barton, Zhao, & Keenan, 2003), thus increasing 4-year-olds' sensitivity to the changes in spacing.

Our results are different from those of two previous studies reporting that 4-year-old children are sensitive to small differences among faces in the spacing of facial features. McKone and Boyer (2006) reported that 4-year-olds were able to select the more distinctive of two faces that differed only in the spacing of features, at least when differences in distinctiveness were medium or large. To create three face sets, they altered the spacing among features and then used adult ratings of distinctiveness to form face pairs in which *differences* in distinctiveness were classified as small, medium, or large. After completing our studies, McKone provided us with the complete set of the stimuli used by McKone and Boyer. We resized McKone and Boyer's stimuli to match ours and then measured how far features were moved when creating the distinctive face. We note several differences between our stimuli and those of McKone and Boyer. First, McKone and Boyer moved the eyes of all but two faces horizontally; the eyes of some faces also were moved vertically. Second, the mean number of pixels by which eyes were moved was larger in all three face sets (small: $M = 16.73$, medium: 15.81, large: 19.38) relative to the horizontal movements used in our current studies (14 pixels). The mean number of pixels by which the mouth was moved was also larger in the McKone and Boyer face sets (small: $M = 8.91$, medium: 8.76, large: 8.13) than in the current study (7 pixels). Third, within each face set, the number of pixels by which features were moved varied (e.g., eyes in the "small differences" face set were moved between 0 and 28 pixels), and within each set, the eyes of some faces were moved at least 20 pixels (4 *SD*). In sum, the average horizontal eye movements used by McKone and Boyer were larger than ours, and some were especially large. We note that despite using larger spacing changes, 4-year-olds' accuracy was low in the McKone and Boyer's study for the large (mean correct = 62%) and medium ($M = 58\%$) face sets and at chance (50%) for the small face set.

The results of our present studies also appear to be inconsistent with those of Pellicano et al. (2006) who showed that altering the spacing of facial features in one part of a face (e.g., the eyes) impairs the ability of 4-year-olds to recognize facial features in the same region or in another part of the face (e.g., the mouth). One possibility is that different task demands lead to differences in children's sensitivity to the spacing among features. In addition, the spacing among facial features in the part/whole task were larger than those used in the current study. Pellicano et al. created two versions of each face (e.g., one version with the eyes moved out and one with the eyes moved in). Those spacing changes were within normal limits and were identical to those used in Experiment 3 of the current study when features were moved horizontally. However, Pellicano et al. did not present the original face on test trials; rather, the model face had eyes moved in one direction (e.g., farther apart) and the test face had eyes moved in the opposite direction (i.e., closer together; L. Pellicano & G. Rhodes, personal communication, November 2007). This is in contrast to our studies in which the original, unaltered version of a face was presented with a spatially altered version in which the eyes were moved in one direction. Consequently, differences in the spacing among facial features were twice as large in the study by Pellicano et al. (approximately 5 *SD*) than in the current study (L. Pellicano & G. Rhodes, personal communication, November 2007).

Our current results also may be surprising in light of recent evidence that 5-month-old infants show sensitivity to differences in the spacing of facial features that fall within normal limits (Hayden, Bhatt, Reed, Corbly, & Joseph, 2007). Hayden et al. (2007) used a visual expectancy procedure in which two stimuli are presented on a screen. The stimuli are stationary for a period of time and then one of the stimuli begins to move; during the first part of the trial, infants look longer at the stimulus that they predict will not move, presumably because they look longer at the moving stimulus during the last part of the trial. Evidence for 7- and 5-month-old infants being sensitive to differences among faces in the spacing of features comes from their successfully predicting which of two faces would move when the pair differed only in the spacing among facial features. Hayden et al. concluded that sensitivity to the spacing among facial features emerges during infancy and they suggested that the 4-year-olds in our previous study in which children were tested with their own face and with faces familiarized via a storybook may have failed because of memory load. This explanation seems unlikely in the current series of studies, however, because there was no memory load either in our distinctiveness tasks or in our matching task. It is possible that 4-year-olds' poor performance when asked to recognize their own face, faces from a storybook (Mondloch et al., 2006), or the face of a close friend (Experiment 3), is due, in part, to memory load. This is of great interest, however, given adults' exquisite memory for the spacing of facial features in highly familiar faces (Ge, Luo, Nishimura, & Lee, 2003); when shown various versions of Chairman Mao's face that differed only in the spacing of features, Mainland Chinese adults were extremely sensitive to small alterations. Their accuracy in reporting which photographs were authentic matched that of Eastern Asian adults who were asked to make same/different judgments about pairs of stimuli from the same set. Nonetheless, memory load cannot completely explain children's poor performance in this series of tasks.

We reconcile our results with those of Hayden et al. (2007) in the following way. The visual system of infants is able to detect differences in the spacing of facial features and infants are able to use that information to predict which of two stimuli is about to move. Presumably, then, the visual system of 4-year-old children is able to detect differences in the spacing of facial features, but 4-year-olds do not use that information to judge distinctiveness or identity even when the spacing of facial features deviates from a more or less average position by up to 3 *SD*—a deviation that samples most of the variability among the faces 4-year-olds will attempt to identify in the real world. We agree with McKone and Boyer (2006) that 4-year-olds' judgments of distinctiveness can be influenced by the spacing among features but only when the spacing changes are quite large. This conclusion is consistent with 4-year-olds' performing well on our criterion trials in which we presented adult female faces and with previous work showing that 8-year-olds' rate these adult faces as grotesque, but their ratings are much lower than those of adults (Mondloch et al., 2004).

Overall, our results provide additional evidence that adult-like sensitivity to small differences among faces in the spacing of features is slow to develop. The ultimate development of sensitivity to the spacing of features is dependent upon visual input during early infancy (Le Grand, Mondloch, Maurer, & Brent, 2001, 2003), but sensitivity to spacing in identity and distinctiveness tasks emerges after 4 years of age—at least when spacing changes are ≤ 2.5 *SD*. We have tested 4-year-olds' sensitivity to the spacing among facial features under a range of task conditions: judgments of distinctiveness, matching facial identity in the absence of memory demands, and recognizing the identity of personally familiar faces. Sensitivity to the spacing among facial features appears to allow adults to recognize a face from a new point of view (Mondloch, Geldart, Maurer, & Le Grand, 2003). Our results predict, therefore, that 4-year-old children may perform poorly when asked to recognize a face from a novel point of view and under other conditions that make featural cues less reliable (e.g., under poor lighting conditions). Under many conditions, however, 4-year-old children will recognize faces with great accuracy; they are very sensitive both to differences among faces in facial contour and in the appearance of individual features (e.g., the eyes and mouth; Freire & Lee, 2001; Mondloch et al., 2006)—other important cues to facial identity. The contribution of sensitivity to other cues known to influence adults' ability to recognize faces (e.g., surface cues such as color and texture; Lee & Perrett, 1997; Russell, Biederman, Nederhouser, & Sinha, 2007) should also be investigated in future studies.

Limitations to Teaching Children 2 + 2 = 4: Typical Arithmetic Problems Can Hinder Learning of Mathematical Equivalence

Nicole M. McNeil
University of Notre Dame

Do typical arithmetic problems hinder learning of mathematical equivalence? Second and third graders (7 – 9 years old; $N = 80$) received lessons on mathematical equivalence either with or without typical arithmetic problems (e.g., $15 + 13 = 28$ vs. $28 = 28$, respectively). Children then solved math equivalence problems (e.g., $3 + 9 + 5 = 6 + \_\_$), switched lesson conditions, and solved math equivalence problems again. Correct solutions were less common following instruction with typical arithmetic problems. In a supplemental experiment, fifth graders (10 – 11 years old; $N = 19$) gave fewer correct solutions after a brief intervention on mathematical equivalence that included typical arithmetic problems. Results suggest that learning is hindered when lessons activate inappropriate existing knowledge.

Some of the most well-known and widely studied phenomena in developmental psychology involve children's failures to learn in seemingly straightforward situations. For example, 3-year-old children continue to sort cards on the basis of one dimension (e.g., color), despite being told repeatedly that they should start sorting according to another dimension (e.g., shape; Zelazo, Frye, & Rapus, 1996), and 9-year-old children continue to hold their initial, incorrect hypotheses about factors that influence the speed of a racecar (e.g., presence of a muffler), even after observing the outcomes of several experiments that yield results to the contrary (Schauble, 1990). Why do children sometimes fail to learn in seemingly straightforward situations, despite substantial instruction? This question has broad theoretical and practical implications. Although it is tempting to attribute children's failures to general conceptual limitations in childhood, several researchers have noted the importance of domain knowledge and basic learning processes in children's failures (see Siegler, 2000).

Here, we focus on children's failures to learn a seemingly straightforward topic in mathematics—mathematical equivalence. *Mathematical equivalence* is the relation between two quantities that are interchangeable. It can be expressed symbolically in the form of a math sentence (e.g., $3 + 4 = 7$) or equation (e.g., $x + 1 = 5$) containing two mathematical expressions separated by the equal sign. The symbolic form implies that the expression on the left side of the equal sign can be replaced by the expression on the right side and vice versa. Although there are nuances that distinguish equivalence from other relations such as equality and identity, these nuances are beyond the scope of the present study. The term *mathematical equivalence* will be used throughout this article because it is the most inclusive and flexible (Kieran, 1981). The term will be used to refer specifically to mathematical equivalence in symbolic form. The key issue here is that we want children to be able to interpret math sentences and equations that contain the equal sign *relationally* as statements of mathematical equivalence because a relational understanding of the equal sign is important for understanding algebra (Carpenter, Franke, & Levi, 2003; Kieran, 1989; Knuth, Stephens, McNeil, & Alibali, 2006).

It is well documented that elementary school children (aged 7 – 11 years) in the United States have substantial difficulty learning to interpret the equal sign as a relational symbol of mathematical equivalence (Baroody & Ginsburg, 1983; Behr, Erlwanger, & Nichols, 1980; Kieran, 1981). Consider, for example, a task in which children are asked to check the "correctness" of math sentences written by a girl or boy who "attends another school." Most children mark sentences such as $10 = 6 + 4$ as "incorrect" and change them to $6 + 4 = 10$, $4 + 6 = 10$, or even $10 +$

This research was supported by an APA Dissertation Award. Portions of these data were presented at the 2004 meeting of the Cognitive Science Society. Preparation of this article was supported in part by Grant R305B070297 from the U.S. Department of Education, Institute of Education Sciences. 6 = 4 (Cobb, 1987; see also Baroody & Ginsburg, 1983; Behr et al., 1980; Rittle-Johnson & Alibali, 1999). Similar misconceptions are also apparent when children are asked to solve addition problems that have operations on both sides of the equal sign (e.g., 3 + 4 + 5 = 3 + __). These problems have been called "mathematical equivalence problems" in prior work (Perry, 1991; Perry, Church, & Goldin-Meadow, 1988). In the absence of instruction, approximately 82% of children (aged 7 – 11 years) solve mathematical equivalence problems incorrectly (McNeil, 2005), and even after receiving instruction, many children continue to have difficulty (Alibali, 1999; Perry, 1991; Rittle-Johnson & Alibali, 1999).

Why do children have trouble learning mathematical equivalence, and how can we help them overcome their difficulties? Contrary to long-established theories of children's (mis)understanding of mathematical equivalence (e.g., Collis, 1974, as cited in Kieran, 1981; Piaget & Szeminska, 1941/1995), it does not appear as though children's difficulties can be attributed to domain general conceptual limitations in childhood. Indeed, children in this age range succeed when asked to identify which pair of numbers (e.g., 3 + 4, 7 + 1, 5 + 6) is equal to a given pair (e.g., 5 + 3), suggesting that they can identify an equivalence relation between two addend pairs (Rittle-Johnson & Alibali, 1999). Children in this age range also are relatively good at solving math equivalence problems when they are presented in a semi-symbolic form in which faces of dice are used in place of the Arabic numerals, and the answer can be chosen from one of four possible answers (Sherman, 2007). Moreover, a majority (~ 90%) of Chinese elementary school children solve math equivalence problems correctly, suggesting that age-related conceptual limitations are not the primary source of children's difficulties (Li, Ding, Capraro, & Capraro, 2008).

The emerging consensus is that children's difficulties with mathematical equivalence are caused, at least in part, by specific knowledge that children construct from their early experience with arithmetic in school (e.g., Baroody & Ginsburg, 1983; Carpenter et al., 2003; McNeil & Alibali, 2005b; Seo & Ginsburg, 2003). In the United States, elementary school mathematics is monopolized by arithmetic (Beaton et al., 1996), which is usually taught in a very procedural fashion with little or no reference to the equal sign or the concept of mathematical equivalence. Moreover, typical arithmetic problems are almost always presented with the operations to the left of the equal sign and the "answer blank" to the right (e.g., 3 + 4 = __; Seo & Ginsburg, 2003), a format that does not highlight the interchangeable nature of the two sides of the equation. This narrow experience with arithmetic leads children to construct overly narrow knowledge structures that do not generalize beyond typical arithmetic problems (McNeil & Alibali, 2005b). Reliance on these knowledge structures, in turn, contributes to difficulties with higher order problems, including math equivalence problems. Note that the claim is not necessarily that experience with arithmetic per se contributes to the difficulties, but rather that experience with arithmetic *as typically taught in U.S. schools* contributes to the difficulties.

Prior work has identified at least three patterns that children learn from their experience with arithmetic in school. These patterns have been called *operational patterns* (McNeil & Alibali, 2005b). First, children learn a perceptual pattern related to the format of math problems, namely, the "operations = answer" format in which the operations are to the left of the equal sign and the answer blank is to the right (McNeil & Alibali, 2004; Seo & Ginsburg, 2003). Second, they learn a concept of the equal sign, namely, that it means "calculate the total" (Baroody & Ginsburg, 1983; Behr et al., 1980; Kieran, 1981; McNeil & Alibali, 2005a). Third, they learn a strategy for solving math problems, namely, "perform all the given operations on all the given numbers" (McNeil & Alibali, 2005b; Perry et al., 1988). With continued practice, children's representations of these operational patterns increase in strength. Subsequently, when these representations are activated in the face of math problems, they guide attention and influence how information is encoded, interpreted, and ultimately applied (cf. Bruner, 1957; McGilly & Siegler, 1990; McNeil & Alibali, 2004). Although this process likely facilitates fast and accurate performance on typical arithmetic problems, it may interfere with performance on problems that deviate from the typical form, such as math equivalence problems.

In accordance with this view, studies have shown that children do, indeed, misapply their knowledge of typical arithmetic problems to math equivalence problems. For example, when asked to reconstruct the problem 3 + 4 + 5 = 3 + __ after viewing it briefly, children rely on their knowledge of the typical "operations = answer" problem format and write "3 + 4 + 5 + 3 = __" (McNeil & Alibali, 2004). When asked to define the equal sign in the problem, children provide answers such as "it means what all the numbers add up to" (McNeil & Alibali, 2005a). When asked to solve the problem, children add up all the numbers and put "15" in the blank. This "add-all" strategy is the most common strategy used by children who have not received instruction on mathematical equivalence (McNeil, 2005; Perry et al., 1988), and use of this strategy increases as the amount of experience with traditional arithmetic increases from first to third grade (McNeil, 2007). Moreover, a recent study has even suggested that children's reliance on their knowledge of these operational patterns may hinder their ability to benefit from a brief one-on-one intervention on math equivalence problems (McNeil & Alibali, 2005b).

Although much of the available evidence supports the hypothesis that children's narrow knowledge of arithmetic hinders learning of mathematical equivalence, experimental evidence is lacking. One exception is an experiment by McNeil and Alibali (2005b, Experiment 2) in which undergraduates' knowledge of arithmetic was activated or was not activated in a control condition. Undergraduates whose knowledge of arithmetic was activated were less likely to perform well on math equivalence problems. This finding is important from a theoretical standpoint because it shows that the activation of arithmetic knowledge can interfere with performance on math equivalence problems. However, the practical significance is limited. The finding indicates that activating *undergraduates'* knowledge of arithmetic hinders *performance* on math equivalence problems in a *laboratory* setting, but we primarily want to know how activating *children's* knowledge of arithmetic affects their *learning* in *classroom* settings. If similar processes affect children's learning of mathematical equivalence, then aspects of the environment that activate and reinforce children's overly narrow knowledge of arithmetic may make it more difficult for children to learn mathematical equivalence.

If the activation of children's knowledge of typical arithmetic problems does indeed hinder children's learning of mathematical equivalence, then teachers may want to avoid lesson contexts that contain typical arithmetic problems when trying to improve children's understanding of mathematical equivalence. Different contexts activate different representations (e.g., Barsalou, 1982), and the context of a typical arithmetic problem activates children's overly narrow representations of the operational patterns (McNeil & Alibali, 2005a; McNeil et al., 2006). Granted, elementary school children may activate these representations to some degree any time they see a math sentence or equation containing the equal sign; however, the likelihood and magnitude of that activation will be greatest in the context of a typical arithmetic problem because the problem maps directly onto the operational patterns (McNeil & Alibali, 2004; McNeil et al., 2006). Once children's knowledge of the operational patterns is activated, children may be less open to information that deviates from these patterns. This perspective suggests a somewhat counterintuitive method of remediation. That is, instead of teaching mathematical equivalence by presenting familiar arithmetic problems such as "2 + 2 = 4" and teaching children that "two plus two is the same amount as four," it might be better to teach mathematical equivalence in a context that does not contain typical arithmetic problems (e.g., present "4 = 4" and teach "four is the same amount as four"). According to this perspective, manipulations of the environment that are designed to activate children's knowledge of typical arithmetic problems should hinder learning of mathematical equivalence.

Although this prediction follows logically from the account that has been advanced thus far, there are also reasons to recommend the opposite. Indeed, intuition suggests that it might be easier for children to learn a new concept in the context of familiar content. Consistent with this view, many educators in the United States hold a review-based instruction philosophy, which assumes that previously learned material provides a supportive scaffold for new learning. This philosophy is evident in math classrooms in the United States where educators often implement a spiral mathematics curriculum in which old information is reintroduced year after year (see Jensen, 1990, for harms associated with the spiral mathematics curriculum). Similarly, several lines of research suggest that the most effective math and science instructions are the ones that "bridge" from children's well-established knowledge to new material (e.g., Bryce & MacMillan, 2005; Clement, Brown, & Zeitsman, 1989; Koedinger & Nathan, 2004; Nathan, Stephens, Masarik, Alibali, & Koedinger, 2002). Both the review-based philosophy and the bridging approach suggest that it may be beneficial for teachers to design lessons that use children's well-established knowledge (e.g., typical arithmetic) as support when introducing a new concept (e.g., mathematical equivalence).

Another reason to expect the presence of typical arithmetic problems to facilitate learning of mathematical equivalence is that it may provide an opportunity for cognitive conflict. Several theories suggest that cognitive conflict promotes learning and cognitive development (e.g., Limon, 2001; Piaget, 1980; VanLehn, 1996). These theories suggest that children will benefit from lessons that purposefully activate their incorrect, operational view of the equal sign and then contradict it. Previous research has shown that typical arithmetic problems such as "3 + 4 = __" activate the operational view (McNeil & Alibali, 2005a; McNeil et al., 2006). Thus, when an educator or parent teaches the relational meaning of the equal sign in the context of a typical arithmetic problem, it may push children into a state of cognitive conflict, which in turn may prompt them to reevaluate their operational view (cf. Limon, 2001).

The goal of the present study was to examine whether the presence of typical arithmetic problems undermines or enhances children's learning from lessons on mathematical equivalence. Children received an intervention that was designed to teach that the mathematical expression on the right side of the equal sign has to be the same amount as (equal to) the mathematical expression on the left side of the equal sign. Elementary school children understand what it means for two amounts to be equal (Rittle-Johnson & Alibali, 1999), so there was potential for them to benefit from this intervention. The intervention was given either in an *arithmetic condition* with typical arithmetic problems or in a *control condition* without typical arithmetic problems. After the intervention, children solved math equivalence problems. If activating children's knowledge of typical arithmetic problems interferes with learning of mathematical equivalence (as predicted), then children should benefit less from the intervention in the arithmetic condition than from the intervention in the control condition. That is, children should solve fewer math equivalence problems correctly after receiving lessons in the arithmetic versus control condition.

Experiment 1

Method

Participants

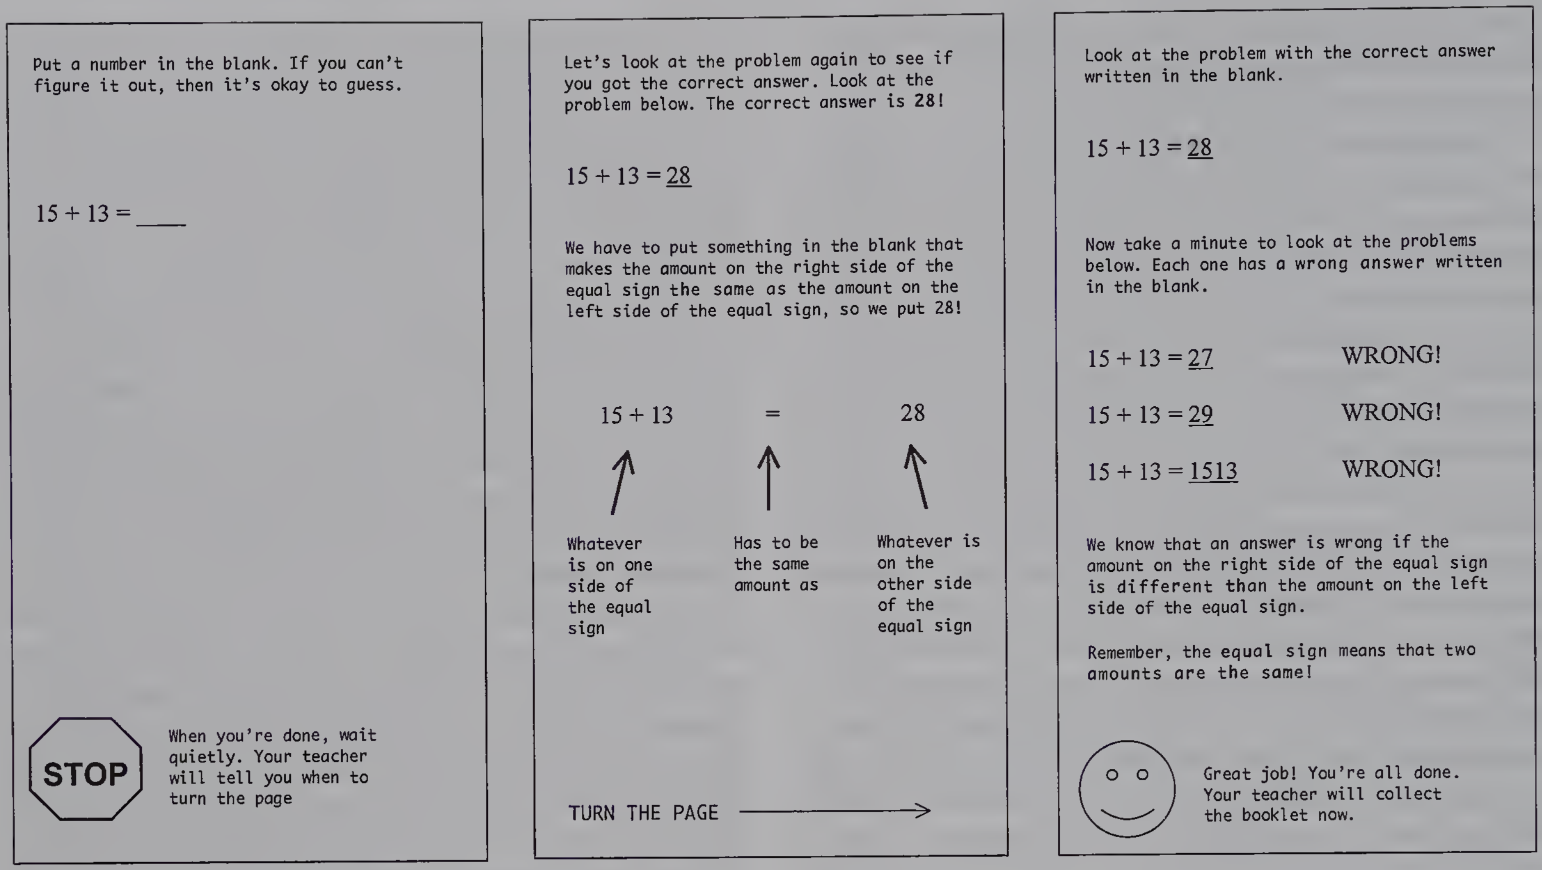
The study was conducted at a public school in a small town near Raleigh, North Carolina. The racial/ethnic makeup of the school was 24% African American, 1% Asian, 6% Hispanic, and 69% White. Approximately 37% of children received free or reduced-price lunch. Ninety-three second- and third-grade children participated. Eleven were excluded because they were absent on one or more days. Two were excluded because their performance was 3 *SD* away from the mean. The final sample contained 80 children (38 boys and 42 girls).

Materials

Scripted lessons on mathematical equivalence in symbolic form. Each daily lesson followed the same basic script, regardless of condition. The script had four main steps. First, teachers read the following instructions: "Today you are going to solve some problems. You may not talk to your neighbor, and you may not look at your neighbor's paper. Don't worry though! It's not a test, so you won't be graded. This is just to see what you think about the problems. If a problem seems too hard for you to solve, then it's okay for you to guess." Second, children were presented with a math problem and asked to solve it. Third, children were presented with a correctly solved version of the problem, and the concept of mathematical equivalence was used to justify the correct answer. Fourth, children were presented with three incorrectly solved versions of the problem, and the concept of mathematical equivalence was used to explain why the answers were wrong. Steps 2–4 were then repeated with a second problem. Children and teachers received booklets to follow along with each daily lesson. The teachers' booklets served as their script for the lessons. Figure 1 shows the script for one problem (15 + 13 = $\underline{28}$) as it was presented in the children's booklets. Given that children worked with different problems across conditions within the same classroom (see the Procedure section), the actual problems were not written in the teachers' booklets. Instead, all problems were replaced with the words "problem is here in students' booklet." With that exception, the teachers' booklets were identical to the children's.

Equation-solving test. Children were given unlimited time to solve 12 math equivalence problems, including 6 "right-blank" problems (e.g., 5 + 4 + 7 = 5 + __, 3 + 9 + 5 = 6 + __) and 6 "left-blank" problems (e.g., 9 + 5 + 7 = __ + 7, 6 + 4 + 8 = __ + 3). Problems of this type have been used extensively in previous research on children's understanding of mathematical equivalence (e.g., Alibali, 1999; McNeil & Alibali, 2005b; Perry et al., 1988). In order to solve these problems correctly without direct instruction on a correct procedure, children must understand that the equal sign is a symbol used to indicate that the mathematical expressions on either side of it are (or are set to be) equivalent. Children also must notice where the equal sign is in the problem and understand the rules for how numbers and operations can be manipulated in order to come up with a solution that makes both sides of the problem have the same value. Children's performance solving math equivalence problems correlates well with other measures designed to assess children's understanding of mathematical equivalence, such as defining the equal sign (Rittle-Johnson & Alibali, 1999) and encoding the structure of equations (McNeil & Alibali, 2004).

Prior to administering the equation-solving test, teachers read the following instructions: "Today we're going to see how well you can solve some problems. Don't worry! It's not a test, so you won't be



Put a number in the blank. If you can't figure it out, then it's okay to guess.

15 + 13 = ____

STOP

When you're done, wait quietly. Your teacher will tell you when to turn the page

Let's look at the problem again to see if you got the correct answer. Look at the problem below. The correct answer is 28!

15 + 13 = 28

We have to put something in the blank that makes the amount on the right side of the equal sign the same as the amount on the left side of the equal sign, so we put 28!

15 + 13 = 28

Whatever is on one side of the equal sign

Has to be the same amount as

Whatever is on the other side of the equal sign

TURN THE PAGE →

Look at the problem with the correct answer written in the blank.

15 + 13 = 28

Now take a minute to look at the problems below. Each one has a wrong answer written in the blank.

15 + 13 = 27 WRONG!

15 + 13 = 29 WRONG!

15 + 13 = 1513 WRONG!

We know that an answer is wrong if the amount on the right side of the equal sign is different than the amount on the left side of the equal sign.

Remember, the equal sign means that two amounts are the same!

Great job! You're all done. Your teacher will collect the booklet now.

graded. I just want you to do your best. After you finish solving the problems, close your booklet and sit quietly until everyone has finished. If a problem seems too hard for you to solve, then don't worry, you can just give it your best guess."

Procedure

The study was conducted over a 2-week period. Children's teachers administered the scripted lessons and collected the measures in the classroom setting. Teachers first taught 2 days of scripted lessons on mathematical equivalence. Lessons were on Tuesday and Thursday, and they lasted approximately 15–20 min each day. Then, children completed the 12 math equivalence problems on the equation-solving test on Friday. The following week, children again received scripted lessons on a Tuesday and Thursday in whichever condition they had not already received (e.g., children who already received lessons in the arithmetic condition now received lessons in the nonarithmetic condition). Finally, children completed the 12 problems on the equation-solving test again on Friday.

All children received the same *spoken* lessons because lessons were scripted. The lessons taught that the amount on the right side of the equal sign has to be the same as (equal to) the amount on the left side of the equal sign. However, children differed according to what they were looking at during the lessons. Children were given booklets to follow along with the lessons, and children were randomly assigned to lesson conditions through the use of these booklets. In the *arithmetic condition*, booklets contained typical arithmetic problems (e.g., 15 + 13 = 28). In the *nonarithmetic condition*, booklets contained problems with the same solution designed to *not* activate knowledge of arithmetic (e.g., 28 = 28). Table 1 presents the problems used in each condition. As can be seen in the table, math equivalence problems were not presented in either lesson condition. Thus, children never received direct instruction on

Table 1
Problems Used in Each Lesson Condition

Arithmetic condition	Nonarithmetic condition
15 + 13 = 28	28 = 28
19–7 = 12	1 foot = 12 inches
6 + 5–8 = 3	●●● = 3
91 + 4 = 95	95 = 95

a procedure for solving math equivalence problems. Figure 2 presents a brief excerpt from each of the lesson conditions as it was presented in students' booklets.

The booklets enabled children *within the same classrooms* to be randomly assigned to conditions. This method of random assignment within classrooms is unique. Typically, teachers are randomly assigned to conditions, and children are nested within teachers. Randomly assigning children within classrooms offers several advantages, including higher power with fewer children and greater assurance that children across conditions are comparable. The development of this new methodology is an important contribution of the present study.

The final sample included 34 children who received lessons in the arithmetic condition first and 46 children who received lessons in the nonarithmetic condition first. No order effects were observed. That is, time point (first or second) did not have significant main effect on performance, and it did not interact with lesson condition to affect performance on equivalence problems (all p values $> .10$). Nonetheless, to ensure the reliability of the reported results, three additional analyses were performed in which 12 of the 46 children who received the nonarithmetic condition first were omitted randomly (to simulate equal n). Conclusions based on the "equal-n" analyses were the same as those reported here.

Coding

Children's performance on the math equivalence problems on the equation-solving test was coded using a system developed by Perry et al. (1988). Children's use of a correct strategy on a given problem was based on an objective criterion—the solution children wrote in the blank. As in past work, children were given credit for using a correct strategy as long as they were within ±1 of the correct answer. For example, on the problem $4 + 8 + 9 = 4 + \_\_$, children would be given credit for using a correct strategy if they put 17, 16, or 18 in the blank.

Results and Discussion

Performance on the equation-solving test was poor. Even after receiving several lessons on mathematical equivalence from their classroom teachers, children solved only 0.73 ($SD = 0.98$) math equivalence problems correctly (out of 12). This poor performance is consistent with prior work (e.g., Alibali, 1999; McNeil & Alibali, 2005b, Experiment 1; Perry et al., 1988), and it highlights just how difficult it is for children to learn and apply mathematical equivalence. Poor performance was characteristic of both second-grade children ($M = 0.69$, $SD = 0.52$) and third-grade children ($M = 0.74$, $SD = 0.83$).

A repeated-measures analysis of variance (ANOVA) was performed with lesson condition (arithmetic or nonarithmetic) as the independent variable and number correct on the equation-solving test (of 12) as the dependent measure. There was a significant main effect of lesson condition, $F(1, 79) = 5.40, p = .023, \eta_p^2 = .06$. As predicted, children solved fewer problems correctly after receiving lessons in the arithmetic condition ($M = 0.56$, $SD = 0.90$) than after receiving lessons in the nonarithmetic condition ($M = 0.89$, $SD = 1.03$). However, it is important to note that children's performance on the math equivalence problems was very poor overall.

Given the potential floor effects, a nonparametric analysis is preferred. Therefore, in accordance with previous studies (e.g., McNeil, 2007; McNeil & Alibali, 2005b), we reanalyzed the data in terms of whether children solved at least one math equivalence problem correctly. Across conditions, 65% of children solved at least one math equivalence

problem correctly. Previous studies have shown a much lower percentage (around 10%–20%) for children in second and third grades who have not received lessons on mathematical equivalence; therefore, this result suggests that the lessons did improve understanding of the symbolic form of mathematical equivalence, albeit weakly. Note that it is not a trivial matter for children to solve one math equivalence problem correctly. Children were free to write any number in the blank. Thus, the probability that children were able to generate the correct answer by guessing is low. Consistent with McNeil (2007), a greater percentage of second-grade children (74%) than third-grade children (60%) solved at least one math equivalence problem correctly.

We examined the effect of lesson condition on performance using a nonparametric test appropriate for repeated measures data. The McNemar test was used to compare children's likelihood of solving at least one math equivalence problem correctly after receiving lessons in the arithmetic condition versus the nonarithmetic condition. Results were consistent with the ANOVA. Of the 46 children who did not solve at least one math equivalence problem correctly after receiving lessons in the arithmetic condition, 18 (39%) solved at least one math equivalence problem correctly after receiving lessons in the nonarithmetic condition; however, only 4 (12%) of the 32 children who did not solve at least one math equivalence problem correctly after receiving lessons in the nonarithmetic condition solved at least one math equivalence problem correctly after receiving lessons in the arithmetic condition, $\chi^2(1, N = 80) = 8.91$, $p = .003$.

In summary, the presence of typical arithmetic problems hindered children's learning from lessons on mathematical equivalence. Given the same verbal lessons, children solved fewer math equivalence problems correctly on average after receiving lessons in the arithmetic condition than after receiving lessons in the nonarithmetic condition, and a smaller percentage of children solved at least one math equivalence problem correctly after receiving lessons in the arithmetic versus nonarithmetic condition. We suspect that the negative effects of the arithmetic condition are due to the overly narrow knowledge structures activated by typical arithmetic problems, specifically knowledge of the "operations = answer" problem format, the "calculate the total" interpretation of the equal sign, and the "perform all the given operations" problem-solving strategy. When these representations are activated, they have the potential to hinder learning of information that does not correspond to the typical form.

Although these results support the hypothesis that the activation of knowledge of typical arithmetic problems hinders learning of mathematical equivalence, there are at least two reasons to be cautious when interpreting the results. First, the experiment compared lessons presented in an arithmetic condition to lessons presented in a nonarithmetic condition. The nonarithmetic condition exposed children to nonstandard equation types (e.g., 28 = 28), which are rarely presented in elementary mathematics instruction (Seo & Ginsburg, 2003). Thus, although we found evidence in support of the hypothesis that the arithmetic condition hinders learning of mathematical equivalence, another plausible interpretation of the results is that the nonarithmetic condition facilitates learning. To rule out this alternative hypothesis, the arithmetic condition would need to be compared to a context-free, control condition. Thus, we tested this comparison in a supplemental experiment (Experiment 2).

The second reason to be cautious is that performance on the math equivalence problems was very poor overall. Children in this age range perform well on typical arithmetic problems in which the goal is to determine the numerical value of several numbers and operations presented on the left side of the equal sign (e.g., 3 + 4 + 5 + 3 = __; McNeil & Alibali, 2004). They also perform well when asked to choose which addend pair (e.g., 1 + 6, 3 + 5, 2 + 4) is equal to a given addend pair (e.g., 4 + 4; Rittle-Johnson & Alibali, 1999). However, they struggle to solve math equivalence problems. The present experiment was no exception. Although the difference between the two lesson conditions in terms of use of a correct strategy was statistically significant and did not depend on the method of analysis, neither condition was very effective in increasing children's use of correct strategies on math equivalence problems. This limitation may be minor from a theoretical standpoint because results supported the hypothesis. Nonetheless, from a practical standpoint, it would be more convincing if the effect could be replicated with a group of children who could reap more benefits from the intervention.

Unfortunately, finding such children is not a trivial task. It is a delicate balance. We need to find children for whom the operational way of thinking about equations is dominant prior to instruction but who, at the same time, are likely to benefit from a brief intervention on mathematical equivalence. One possible solution is to screen older, more experienced children. Children who have more experience with a variety of mathematics topics (e.g., equivalent fractions, magnitude comparison problems) are less entrenched in the operational way of thinking

(McNeil, 2007). They have the potential to exhibit both operational and relational ideas about equations depending on the context (McNeil & Alibali, 2005a; McNeil et al., 2006), so they should be more open to a brief intervention on mathematical equivalence. However, there may also be drawbacks to working with older children. Namely, it may be difficult to find older, more experienced children for whom the operational way of thinking about equations is dominant. Although older children continue to exhibit operational ideas about equations that hinder understanding of higher order math topics in middle school and beyond (Kieran, 1981; Knuth et al., 2006; McNeil & Alibali, 2005b; McNeil et al., 2006), they also exhibit relational ideas about equations in certain contexts (McNeil & Alibali, 2005a; McNeil et al., 2006) and solve math equivalence problems correctly (McNeil, 2007). It is crucial to work with children who still maintain the operational way of thinking about equations as their dominant view, so we can examine which conditions encourage (or discourage) children from moving beyond that view. At the same time, we need to work with children who have more experience with a broader array of mathematics topics so we can increase the likelihood that they will be more open to an intervention than were the children in Experiment 1. Thus, we screened for such children in Experiment 2.

Experiment 2

Experiment 2 was designed to address two specific goals. First, we sought to compare the arithmetic condition to a control condition that did not include nonstandard equations. Second, we sought to test a group of older children who still exhibited the operational way of thinking about equations as their dominant view. We expected these children to be more likely than the second- and third-grade children to use correct strategies on math equivalence problems after a brief intervention.

Method

Participants

The study was conducted at a suburban public school in Connecticut. The racial/ethnic makeup of the school was 3% African American, < 1% Asian, 2% Hispanic, and 94% White. Approximately 10% of children received free or reduced-price lunch. The children were selected from 57 fifth-grade children who received consent to participate. Of those children, 19 (11 boys and 8 girls) met criteria for participation because they interpreted the equal sign as an arithmetic operation on the pretest (see the Coding section for details). Of the 38 children who did not meet the criteria, 31 had other incorrect interpretations of the equal sign, and 7 had a relational interpretation of the equal sign. The average reported math grades of children who met criteria for inclusion did not differ significantly from the average reported math grades of children who did not meet criteria, $F(1, 55) = 0.80$, $p = .37$.

Measures

Pretest measure of equal sign understanding. The measure of equal sign understanding was modeled after measures used in previous work (e.g., Knuth et al., 2006; McNeil & Alibali, 2005a; Rittle-Johnson & Alibali, 1999). There was an arrow pointing to the equal sign followed by two questions: (a) "The arrow above points to a symbol. What is the name of the symbol?" and (b) "What does the symbol mean?" This measure has good convergent validity (e.g., McNeil & Alibali, 2005a) and good concurrent validity (e.g., Knuth et al., 2006).

Equation-solving posttest. Children were given unlimited time to solve 4 right-blank math equivalence problems: $5 + 4 + 8 = 5 + \_\_$, $4 + 8 + 9 = 4 + \_\_$, $3 + 9 + 7 = 6 + \_\_$, and $9 + 4 + 6 = 3 + \_\_$. We used 4 problems instead of 12 in favor of efficiency because past work has shown similar performance regardless of whether children solve 3 (e.g., McNeil & Alibali, 2000), 4 (e.g., Rittle-Johnson & Alibali, 1999), or greater than 4 math equivalence problems (e.g., Experiment 1; Alibali, 1999; McNeil & Alibali, 2004; Perry, 1991; Perry et al., 1988). We used only right-blank problems because several studies have used only right-blank problems (e.g., McNeil & Alibali, 2000; Rittle-Johnson & Alibali, 1999), and children in prior studies have been equally likely to use incorrect strategies on right- and left-blank problems (e.g., McNeil & Alibali, 2004). Indeed, children's use of a correct problem-solving strategy does not seem to depend on (a) the location of the missing addend, (b) the symbol used in place of the missing addend (__ vs. □), or (c) the number of addends on the left side of the problem (see Carpenter et al., 2003; Ding et al., 2007). Children are just as likely to use an incorrect strategy on the problem $5 + 4 + 8 = 5 + \_\_$ as they are on the problem $\square + 8 = 12 + 5$.

Procedure

The experiment was held in school during regular school hours. Children were given the pretest measure, the intervention, and the posttest measure as paper-and-pencil worksheets in a large-group setting. First, children completed the pretest measure of equal sign understanding. Then, they were randomly assigned to one of two brief interventions on the meaning of the equal sign. Figure 3 displays the two interventions as children saw them. As shown in the figure, the interventions taught the same information about the equal sign—the amounts on both sides have to be the same value. Both interventions contained this conceptual information about the meaning of the equal sign. The factor that was manipulated between the interventions was the context in which the equal sign was presented. In the *arithmetic context*, the equal sign was presented in the context of a typical arithmetic problem (e.g., $3 + 4 = \underline{7}$). In the *alone context*, the equal sign was presented alone, without any associated math context (e.g., =). The alone context was used instead of the nonstandard equation types that were used in Experiment 1 (e.g., $28 = \underline{28}$) to ensure that any differences between conditions could be attributed to the negative effect of the typical arithmetic problems and not to the beneficial effect of nonstandard equation types.

Coding

Equal sign understanding. Children's responses on the pretest measure of equal sign understanding were coded based on the system used by McNeil and Alibali (2005b). This system differs from previous coding systems (e.g., McNeil & Alibali, 2005a; Rittle-Johnson & Alibali, 1999) because it distinguishes between different types of incorrect definitions of the equal sign. Specifically, it distinguishes children who mention arithmetic operations and/or arithmetic symbols in their definitions (e.g., "it means you need to add, subtract, multiply, or divide") from children who do not (e.g., "it means what the question is"). We know that children who mention arithmetic operations and/or arithmetic symbols in their definitions are more deeply entrenched in the operational view of equations than are children who provide other incorrect definitions of the equal sign (McNeil & Alibali, 2005b). Because our goal in the present experiment was to work with older children who are still entrenched in the operational view, we specifically screened for children who mentioned arithmetic operations and/or arithmetic symbols in their

definitions of the equal sign. Reliability was established by having a second coder evaluate the interpretations of a randomly selected 20% sample ($N = 11$). Agreement between coders was 100%.

Equation-solving performance. Coding of equation-solving performance was identical to that in Experiment 1.

Results and Discussion

The fifth-grade children's performance on the equation-solving test was relatively good compared to the performance of second- and third-grade children in Experiment 1. After receiving the brief intervention on the meaning of the equal sign, children solved 2.10 ($SD = 1.97$) math equivalence problems correctly (out of 4). This finding is consistent with recent work showing that performance on math equivalence problems is better after age 9 (McNeil, 2007). An ANOVA was performed with intervention context as the independent variable and number correct on the equation-solving measure (out of 4) as the dependent measure. Children who received the intervention in the typical arithmetic context solved fewer problems correctly than did children who received the intervention in the alone context ($M = 1.00$, $SD = 0.50$ vs. $M = 3.10$, $SD = 0.42$), $F(1, 17) = 7.26$, $p = .01$, $\eta_p^2 = .30$. Thus, there was a large effect of intervention context on performance (as indicated by the effect size). Another way to analyze the data is to use a nonparametric test to examine whether condition affects whether or not children ever solved at least one math equivalence problem correctly. Only 3 of 9 children (33%) solved at least one math equivalence problem correctly after receiving the intervention in the arithmetic context, whereas 8 of 10 children (80%) solved at least one math equivalence problem correctly after receiving the intervention in the alone context, $\chi^2(1, N = 19) = 4.23$, $p = .04$.

Taken together with the results of Experiment 1, these findings support the hypothesis that the activation of children's knowledge of typical arithmetic problems hinders their learning of mathematical equivalence. When a typical arithmetic problem is present in the environment, it activates children's representations of the operational patterns. The activation of these representations, in turn, hinders learning of information that deviates from the typical arithmetic form. Findings suggest that learning of mathematical equivalence is hindered when overly narrow knowledge of typical arithmetic is activated. The potential processes involved in these effects and the implications are discussed in the next section.

General Discussion

Over 20 years of research suggests that children's difficulties with mathematical equivalence are caused, at least in part, by specific knowledge that children construct from their narrow experience with typical arithmetic problems in school (e.g., Baroody & Ginsburg, 1983; Carpenter et al., 2003; McNeil, 2007). According to this view, children should have more difficulty learning mathematical equivalence when their narrow knowledge is activated than when it is not activated. The present study was the first to test this hypothesis experimentally. In Experiment 1, second- and third-grade children were less likely to solve math equivalence problems (e.g., $3 + 9 + 5 = 6 + \_\_$) correctly after receiving lessons in the presence of typical arithmetic problems than after receiving lessons in the presence of other math problems. In Experiment 2, fifth-grade children who still interpreted the equal sign as an arithmetic operation solved fewer math equivalence problems correctly after receiving an intervention in the presence of typical arithmetic problems than after receiving an intervention in the presence of the equal sign alone. Both experiments support the hypothesis that the presence of typical arithmetic problems hinders learning of mathematical equivalence.

Given the theoretical and practical implications of these findings, it is important to understand the processes that may account for the observed effects. The explanation that has been advanced throughout this article is that the presence of typical arithmetic problems hinders learning because typical arithmetic problems activate overly narrow representations that do not generalize broadly. Specifically, typical arithmetic problems are thought to activate children's representations of (a) the "operations = answer" problem format, (b) the "calculate the total" interpretation of the equal sign, and (c) the "perform all the given operations" problem-solving strategy (McNeil & Alibali, 2005b). When these representations are activated, they have the potential to influence how information is encoded, interpreted, and used (cf. Bruner, 1957; McGilly & Siegler, 1990); therefore, information that does not map onto the patterns may not be learned as well as it could be in the absence of those activated representations. Although the results of the present study support this account, they do not rule out the possibility that other processes may have played a role in the observed effects.

For example, in addition to activating children's representations of specific patterns that interfere with learning (e.g., "operations = answer" problem format), the presence of typical arithmetic problems may trigger a more general cognitive bias, or mindset, that leads children to be inattentive to instructional input. Specifically, typical arithmetic problems may promote *mindlessness*, which has been defined as being committed to a "single, rigid perspective and . . . oblivious to alternative ways of knowing" (Langer, 2000). Mindlessness is a general state of mind that reduces individuals' sensitivity to the environment. Instead of noticing novel aspects of the environment and actively constructing strategies that apply to the current situation, mindless problem solvers are content to rely on the strategies they have used many times in the past. In the current study, the presence of typical arithmetic problems may have promoted mindlessness because children have seen and solved typical arithmetic problems many times in the past. If this is the case, then children may have been less attentive to the lessons in the arithmetic condition than in the control condition in both experiments.

It is also possible that some other systematic difference between the arithmetic and the control conditions (other than the presence of typical arithmetic problems per se) contributed to the observed effects. In Experiment 1, the control condition included nonstandard math sentences such as 28 = 28. These nonstandard math sentences may facilitate learning of mathematical equivalence. If this is the case, then the findings of Experiment 1 could be attributed to the beneficial effect of nonstandard math sentences, rather than to the negative effect of typical arithmetic problems. To rule out this alternative explanation, the control condition in Experiment 2 did not include nonstandard math sentences. Results were consistent with Experiment 1; however, the possibility remains that some other factor varied systematically between the arithmetic and control conditions across experiments.

For example, the stimuli in the arithmetic and control conditions differed in terms of novelty. Children rarely see the equal sign presented by itself or in the context of nonstandard math sentences (Seo & Ginsburg, 2003); therefore, the stimuli presented in the control conditions were less familiar to children than were the stimuli presented in the arithmetic conditions. This novelty alone may have improved children's performance by increasing children's attention to the equal sign either during the lessons or during the equation-solving test, or both. Increasing children's attention to the equal sign has been shown to affect children's strategy choices on math equivalence problems (Alibali, McNeil, & Perrott, 1998). However, increased attention to the equal sign cannot, by itself, account for better performance in the control conditions because prior work has shown no evidence that it affects use of *correct* strategies (Alibali et al., 1998). Another factor that varied between the two conditions was the amount of exposure to numbers. There were more numbers in the arithmetic conditions than in the control conditions. It is possible that the preponderance of numbers increased children's attention to the numbers at the expense of other important features of the lessons. This increased attention to the numbers also may have hurt performance by carrying over to the equation-solving test. If children attended only to the numbers and ignored the location of the equal sign, then they would not have been able to solve the math equivalence problems correctly. Obviously, there is much work to be done before we fully understand the processes involved in the observed effects. Nonetheless, the current study is valuable because it provides the first evidence that children benefit less from a lesson on mathematical equivalence in the presence of typical arithmetic problems than in the presence of either nonstandard math sentences or the equal sign alone. This finding has potential implications for mathematics classrooms.

Educational Implications

The current study adds to the debate about the most effective ways to teach children new information that diverges from their well-established knowledge. Nathan et al. (2002) argue that the most effective instructions are ones that "bridge" from children's well-established knowledge to new material (see also Bryce & MacMillan, 2005; Clement et al., 1989; Koedinger & Nathan, 2004), and some researchers suggest that it is especially beneficial to activate children's incorrect knowledge during instruction because it provides an opportunity for cognitive conflict (Limon, 2001; Piaget, 1980; VanLehn, 1996). However, the present results suggest that it may not always be a good idea to activate children's well-established knowledge. In some cases, the activation of well-established knowledge may hinder children's learning of new information. Teachers may want to avoid activating well-established knowledge in these cases. Specifically, teachers may want to avoid activating children's well-established knowledge of typical arithmetic problems when teaching higher order topics such as mathematical equivalence.

If the activation of children's knowledge of arithmetic contributes to children's difficulties learning mathematical equivalence, then it may be the case that children who are most proficient with typical arithmetic problems are slowest at developing an understanding of algebraic concepts. Consistent with this view, children with the strongest representations of the typical arithmetic patterns have the most difficulties learning from a one-on-one lesson on mathematical equivalence (McNeil & Alibali, 2005b). This hypothesis conflicts with intuition and traditional mathematics practices. Intuition suggests that children who are best at one math topic should be best at another math topic. And indeed, most schools assign, or track, children to algebra based on their performance in arithmetic. This policy is based on theories that suggest that children need to be proficient with "basic" arithmetic facts to be successful at algebra (e.g., Haverty, 1999; Haverty, Koedinger, Klahr, & Alibali, 2000; Kaye, 1986; McKeown, 2002). However, this policy might not be the best approach if children's overly narrow knowledge of arithmetic hinders learning of algebra. Future research in our lab will examine how proficiency with typical arithmetic problems affects understanding of algebra.

Do results of the present experiments imply that teachers should stop teaching arithmetic? Certainly not, but they do suggest that teachers may want to consider alternative approaches to teaching arithmetic. For example, instead of reintroducing arithmetic procedures every year and restricting algebra to a course in eighth or ninth grade, educators could integrate more algebraic ways of thinking into elementary school mathematics, starting in first grade as recommended by many math education researchers (e.g., Blanton & Kaput, 2003; Carpenter & Levi, 1999; National Council of Teachers of Mathematics, 2000). One strategy for doing this is to focus instruction on mathematical equivalence (Carpenter et al., 2003). For example, instead of simply practicing typical arithmetic "facts" such as "3 + 4 = 7," children can learn "7 = 3 + 4," "3 + 4 = 5 + 2," and "7 = 7." Approaches such as this may prevent the entrenchment of overly narrow knowledge of arithmetic in the first place and facilitate the notoriously difficult transition from arithmetic to algebra. We are currently testing the benefits of practice with nonstandard arithmetic problems.

Critics may argue that the entrenchment of overly narrow knowledge of arithmetic is not an important educational problem because performance on math equivalence problems tends to improve after age 9 (McNeil, 2007). In line with this view, the fifth-grade children in Experiment 2 performed reasonably well on math equivalence problems after only receiving a brief intervention. However, it may be possible for older children to improve their performance on math equivalence problems without developing a sophisticated understanding of mathematical equivalence. Indeed, children can learn to perform well on problems despite substantial limitations in their conceptual knowledge (Sophian, 1997). We know that representations of the overly narrow operational patterns continue to coexist along side correct understandings of mathematical equivalence in middle school and beyond (McNeil & Alibali, 2005a, 2005b; Experiment 2). The activation of these overly narrow representations may contribute to many of the difficulties that older students have when working with symbolic expressions and equations in algebra (Carpenter et al., 2003; Kieran, 1981; Knuth et al., 2006). For example, failure to interpret the equal sign relationally may contribute to middle school students' difficulties solving algebraic equations such as $4m + 10 = 70$ (Knuth et al., 2006). Similarly, commitment to the "operations = answer" format may contribute to high school students' difficulty understanding algebraic expressions that do not contain an equal sign such as $3a$, $a + 3$, and $3a + 5a$ (Kieran, 1981). For these reasons among others, it is important to study the best ways to help children overcome their overly narrow views of arithmetic.

Methodological Advancement

One of the primary contributions of the present study is a new methodology for studying factors that affect children's learning. Since the Education Sciences Reform Act of 2002, the establishment of the Institute of Education Sciences, and the publication of *Scientific Research in Education* (National Research Council, 2002), researchers have increased their efforts to apply experimental methods to the study of educational problems. However, it is difficult to perform rigorously controlled experiments in schools. At the same time, educators are highly skeptical of rigorously controlled experiments that occur outside of schools (in laboratories) because they are often small in scale and do not involve the complexities encountered in real-life educational settings. The design used in Experiment 1 provides a way to implement the rigorous control of a laboratory experiment within the context of a classroom.

In Experiment 1, lesson booklets were used to randomize children within classrooms to conditions, and teachers were given a script that applied to both conditions. This method allowed researchers to have a high degree of control over what children saw and heard during the study (similar to the laboratory setting). At the same time, teachers administered the lessons and collected all measures in a typical classroom setting. Of course, critics of classroom-based *experiments* may argue that the booklet format provides a shallow imitation of the rich lessons that teachers should be implementing in the classroom, and critics of *classroom-based* research may argue that the experiment was not as systematic and controlled as it would have been if it were performed one-on-one in the laboratory. Given the large gulf between these two camps, the booklet methodology seems to offer a good compromise. Researchers who are interested in children's learning may want to consider including within-classroom randomization in their methodological toolkit.

Concluding Remarks

The present findings contribute to our understanding of the processes involved in children's failures to learn in seemingly straightforward situations. Such failures historically have been attributed to general conceptual limitations in childhood. However, the current study adds to a growing literature that emphasizes the role of domain knowledge and basic learning processes in children's failures. Results suggest that children's learning failures may be caused, at least in part, by the activation of well-established knowledge. Because many studies focus on how knowledge helps learning (e.g., Rittle-Johnson, Siegler, & Alibali, 2001), situations in which knowledge hinders learning provide a unique window into how the mind works. Future research efforts should be devoted to developing a general framework for understanding when knowledge helps versus hinders learning. By studying how existing knowledge plays a role in the acquisition of new information, researchers can inform both our understanding of how humans acquire knowledge and our efforts to modify the external environment to enhance children's learning and development.

Perception of Dynamic and Static Audiovisual Sequences in 3- and 4-Month-Old Infants

David J. Lewkowicz
Florida Atlantic University

This study investigated perception of audiovisual sequences in 3- and 4-month-old infants. Infants were habituated to sequences consisting of moving/sounding or looming/sounding objects and then tested for their ability to detect changes in the order of the objects, sounds, or both. Results showed that 3-month-olds perceived the order of 3-element sequences and that 4-month-olds perceived the order of 3- and 4-element sequences. In addition, results indicated that perception of moving sequences was more robust than of looming ones and that detection of order differences was not based on primacy cues. The current results show that perception of multisensory sequences and their structure emerges early in development, and a preliminary model of the development of sequence perception is offered.

The ability to perceive, learn, and produce sequences provides the foundation for many behavioral functions (Keele, Ivry, Mayr, Hazeltine, & Heuer, 2003; Lashley, 1951; Martin, 1972; Zacks & Tversky, 2001). For example, our ability to tell that the utterance "the boy kissed the girl" differs from the utterance "the girl kissed the boy" depends on the fact that we can tell that the same words are ordered differently in the two phrases. Likewise, our ability to hear two differently ordered sequences of identical musical notes as different melodies depends on our ability to detect the ordering of the notes. Finally, our ability to execute a series of hand and arm movements when driving a car depends on the fact that we are able to assemble the required component actions into the appropriately ordered sequence. These examples make it clear that our ability to detect the particular ordering of a series of sequence elements is key to discovering the "hidden" meanings inherent in different types of events and that our ability to concatenate a series of motor acts into a correctly ordered action sequence is key to producing adaptive behaviors.

Given the fundamental importance of the ability to perceive, learn, and produce sequences, there is little doubt that understanding its development can provide critical insights into the development of basic perceptual, cognitive, and social skills (Greenfield, 1991; Nelson, 1986). Piaget (1952) recognized this fact and conducted careful observations to determine whether and when infants might be able to produce sequences of behavioral actions to achieve specific goals. He found that infants as young as 8 months of age could string together a series of discrete motor acts into adaptive action sequences. More recent empirical investigations have supported Piaget's observations by showing that the ability to produce action sequences emerges early in life. Specifically, these investigations have shown that (a) 4-month-old infants can engage in turn taking when interacting with adults (Jaffe, Beebe, Feldstein, Crown, & Jasnow, 2001); (b) 3-month-old infants can learn to move a series of three mobiles in a particular sequence and can remember the order in which they moved them 24 hr later (Merriman, Rovee-Collier, & Wilk, 1997); (c) 6-month-old infants can learn to move a series of as many as five mobiles in a particular sequence (Gulya, Sweeney, & Rovee-Collier, 1999); (d) 9-month-old infants can learn, remember, and reproduce multiact manual sequences in the correct sequential order as long as the acts are related in obvious ways (Bauer, Wiebe, Waters, & Bangston, 2001; Carver & Bauer, 1999); and (e) 22-month-old children can learn and remember multiact sequences even when the acts are arbitrarily related (Bauer, Hertsgaard, Dropik, & Daly, 1998).

A number of other studies have investigated whether infants can perceive and learn sequences. Like the studies on sequence production, these

studies have found that infants can, indeed, perceive and learn sequences. Specifically, they have shown that (a) 5-month-old infants can learn and then recall the sequential arrangement of a series of four static images (Smith, Loboschefski, Davidson, & Dixon, 1997), (b) 8-month-old infants can learn statistical (i.e., transitional probability) relations among adjacent sounds (Saffran, Aslin, & Newport, 1996; Saffran, Johnson, Aslin, & Newport, 1999), (c) 2- to 8-month-old infants can learn statistical relations among adjacent visual stimuli (Kirkham, Slemmer, & Johnson, 2002), (d) 9-month-old infants prefer speech strings and monosyllabic nonwords that follow legal phonotactic adjacency rules (Jusczyk, Friederici, Wessels, Svenkerud, & Jusczyk, 1993; Jusczyk, Luce, & Charles-Luce, 1994), (e) 7- to 12-month-old infants can learn simple grammatical rules for sequences of sounds (Gómez & Gerken, 1999; Marcus, Vijayan, Rao, & Vishton, 1999), and (f) 15- to 18-month-old infants can learn distant sequential relations specifying a series of sounds (Gómez, 2002; Gómez & Maye, 2005).

Interestingly, when the findings on infant ability to perceive and learn sequences are considered together, they clearly demonstrate that language is not necessary for the development of sequence perception and learning. Indeed, this conclusion is supported by findings from studies of nonhuman primates showing that monkeys also not only can learn sequences but that they can generalize across sequences composed of different elements and, thus, can learn ordinal position information as well as syntax-like rules (Chen, Swartz, & Terrace, 1997; Hauser, Weiss, & Marcus, 2002; Orlov, Yakovlev, Hochstein, & Zohary, 2000; Terrace, 1993; Terrace, Son, & Brannon, 2003).

Overall, the extant empirical findings indicate that the ability to produce organized action sequences and perceive sequential relations emerges very early in life, that it improves rapidly in early development, and that infants' ability to perceive sequences is quite general because they can perceive and learn sequences specified in the auditory as well as the visual modalities. Given these facts, it is reasonable to suppose that the early emerging ability to perceive sequences contributes in important ways to the development of higher level perceptual and cognitive skills. The most likely way in which it does so is by providing the necessary early perceptual and developmental foundation for the subsequent discovery of the hidden sequential structure underlying most events. For example, in language development, infants probably initially discover the ordered and then syntactic structure underlying sequences of sounds, and once they do so, they can then proceed to discover the hidden meanings that are inherent in such sequences of sounds. If such a progressive developmental scenario is general in nature, then a similar pattern might be observed in the development of event perception. That is, infants probably initially discover the ordered and then causal relations among sequence elements, and once they do so, they then can proceed to discover the hidden meanings inherent in particular events.

It is interesting to note that most of the events in an infant's daily life are specified by multisensory attributes that are typically redundant. For example, when infants see and hear a person talking, or when they see and hear a ball bouncing, they have access to synchronous auditory and visual sensory attributes that correspond in terms of their duration, tempo, and rhythmic patterning. It is also interesting to note that multisensory redundancy increases perceptual salience and facilitates perception, learning, and discrimination in human adults (Hershenson, 1962; McGurk & MacDonald, 1976; Summerfield, 1979; Welch & Warren, 1980), animal adults (Partan & Marler, 1999; Rowe, 1999; Stein & Meredith, 1993), and human infants (Bahrick & Lickliter, 2000; Lewkowicz & Kraebel, 2004; Neil, Chee-Ruiter, Scheier, Lewkowicz, & Shimojo, 2006; Scheier, Lewkowicz, & Shimojo, 2003). As a result, it is important to investigate infant response to multisensory event sequences if we are to gain deeper insights into the development of sequence perception and learning.

Only one study to date has investigated infant response to multisensory sequences specified by auditory and visual attributes (Lewkowicz, 2004) and, as might be expected, found that multisensory redundancy did, in fact, enhance young infants' response. Specifically, in this study, infants were habituated to a sequence of three moving objects and their concurrent impact sounds and then were tested in separate test trials to determine whether they could detect changes in the serial order of the objects, the impact sounds alone, or the objects and their concurrent impact sounds. Results indicated that 4-month-old infants detected serial order changes only when they were specified concurrently by audible and visible attributes but that 8-month-old infants detected the changes regardless of whether they were specified concurrently by the audible and visible attributes or by just one of them.

Although the Lewkowicz (2004) study provided evidence that infants can learn and discriminate dynamic audiovisual sequences, it also raised some key questions. First, a general sensitivity to temporal and dynamic information—the essential underlying basis for learning dynamic audiovisual sequences—emerges earlier than 4 months of age (Kellman &

Arterberry, 1998; Lewkowicz, 1989, 2000), thus raising the question of whether infants younger than 4 months of age might be able to learn audiovisual sequences. Second, the sequences presented in the Lewkowicz (2004) study differed in terms of their initial objects/sounds, raising the question of whether this difference made discrimination possible. Third, because sensitivity to visual motion emerges very early in infancy (Bertenthal, Proffitt, Kramer, & Spetner, 1987; Dannemiller & Freedland, 1991; Kaufmann-Hayoz, Kaufmann, & Stucki, 1986; Kaufmann, Stucki, & Kaufmann-Hayoz, 1985; Shea & Aslin, 1990) and because motion contributes to object perception in infancy (Kellman & Spelke, 1983; Kellman, Spelke, & Short, 1986), this raises the question of whether motion might play a role in infant perception of dynamic audiovisual sequences. Finally, studies have shown that infants are sensitive to visual sequence complexity (Canfield & Haith, 1991; Gulya, Rovee-Collier, Galluccio, & Wilk, 1998; Gulya et al., 1999), thus raising the question of whether infants also are sensitive to audiovisual sequence complexity?

The purpose of the current study was to answer the four questions outlined above in separate experiments. Thus, Experiment 1 investigated whether 3-month-old infants can perceive and discriminate dynamic audiovisual sequences by presenting the identical stimuli and using the same testing procedures as in the Lewkowicz (2004) study. Experiment 2 investigated whether primacy effects might contribute to discrimination of audiovisual dynamic sequences by presenting contrasting sequences whose initial sequence elements were held constant. Experiment 3 investigated whether motion may contribute to perception and discrimination of dynamic audiovisual sequences by presenting sequences consisting of looming/sounding objects. Finally, Experiment 4 examined the effects of sequence length/complexity by testing infants' ability to perceive and discriminate four-element sequences.

Experiment 1

Studies have shown that infants younger than 4 months of age can learn sequences. For example, Canfield and Haith (1991) presented sequences consisting either of symmetrically or of asymmetrically alternating visual stimuli and found that 2-month-old infants learned to anticipate symmetrical sequences and that 3-month-old infants learned to anticipate asymmetrical sequences as well. Gulya et al. (1998) used the mobile conjugate reinforcement procedure to train 3-month-old infants to move a series of different mobiles and found that infants could learn to move a series of three mobiles and then remember the order in which they moved them a day later. Finally, Kirkham et al. (2002) found that infants as young as 2 months of age could quickly learn the statistical relations specifying a series of visual shapes. When these findings are considered together with the fact that sensitivity to temporal information and to visual motion emerges prior to 4 months of age (Lewkowicz, 1989, 2000), they suggest that infants younger than 4 months of age should be able to perceive, learn, and discriminate dynamic audiovisual sequences. The purpose of this experiment was to test this prediction by investigating 3-month-old infants' response to the same dynamic audiovisual sequences presented by Lewkowicz (2004) to 4- and 8-month-old infants.

Method

Participants. Twenty-four 3-month-old infants (M age = 14.7 weeks, SD = 0.7 weeks; 12 boys and 12 girls) contributed data in this experiment. Three additional infants were tested but were not used because they were inattentive. The infants in this experiment, as well as in all the subsequent ones, were full term at the time of birth, had birth weights above 2,500 g, had 1- and 5-min Apgar scores of 7 or higher, had no prenatal or perinatal complications, and were healthy at the time of testing. The ethnic proportions of the participants in all the experiments reported here were approximately 5% Hispanic, 77% non-Hispanic, and 18% unreported. The corresponding racial proportions were 4% Black or African American, 0% Asian, 3% more than one race, 73% White or Caucasian, and 20% unreported.

Apparatus and stimuli. All stimulus events were multimedia movies. One movie showed an attention-getter, which was an expanding and contracting green disk. A second movie, used to test for possible fatigue effects, showed a segment of a Winnie the Pooh cartoon. It was presented at a sound pressure level (SPL) of 70-74 dB against an ambient SPL of 50 dB. The remaining four movies showed different sequential orderings of three different moving objects and their distinct impact sounds. Each of these movies showed the three objects seen in Figure 1a (Object A—circle, Object B—triangle, and Object C—square) emerging one after the other from a spout at the top of the stimulus presentation monitor. The objects moved down, and when they reached the bottom of their downward path, they contacted a black ramp (part of which was not visible in this experiment), made an impact sound, turned to the right, and moved off to

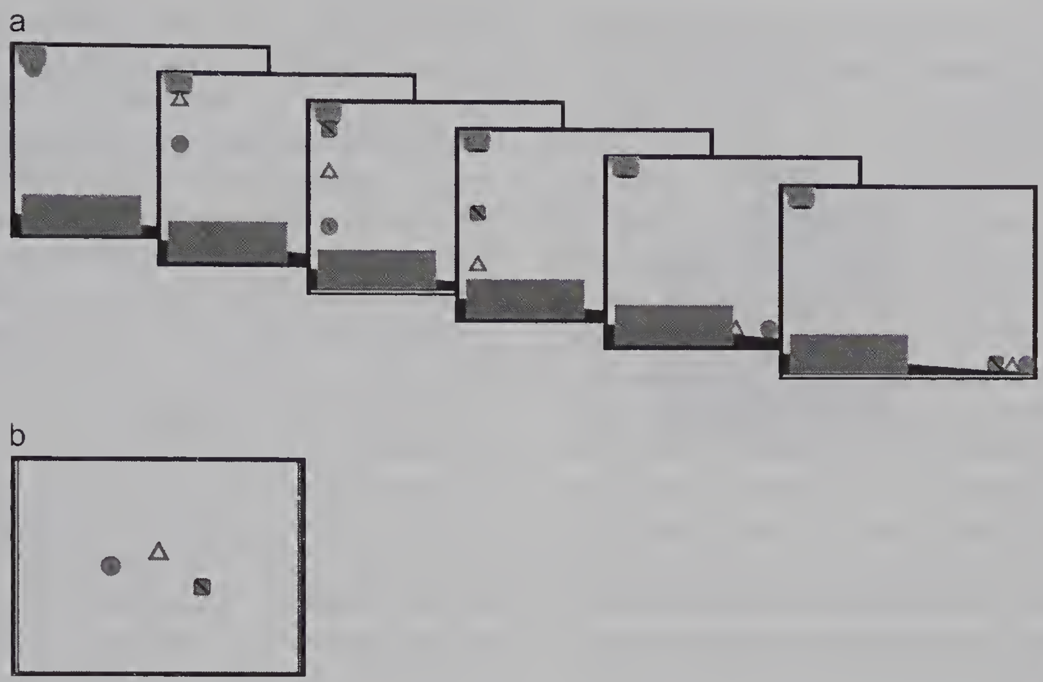

Figure 1. (a) The three objects and the schematic representation of their movement over time in Experiment 1. (b) The spatial arrangement of the three objects in Experiment 3.

the side (the objects did not pause when they made their impact sound). The impact sounds were ".wav" files that are part of the Microsoft Windows 98 operating system and corresponded to the three objects as follows: Object A—JungleSingDrumMono.wav, Object B—UtopiaDink.wav; and Sound C—SportsPPongMono.wav. The movies consisting of the moving/sounding objects represented the four possible combinations of object and/or sound ordering. They were as follows: auditory-ABC/visual-ABC, auditory-CAB/visual-ABC, auditory-ABC/visual-CAB, and auditory-CAB/visual-CAB. All movies were presented on a 17-in. computer monitor at a distance of 50 cm from the infant. At this distance, the objects subtended a mean of 2.86° of visual angle (the angular size is reported as an average because the objects varied very slightly in their size). The audio part of the movie was presented through two speakers placed on each side of the monitor. The mean SPL of the impact sounds was 80 dB (A scale) against an ambient SPL of 50 dB.

As shown in Figure 1a, each movie began with the appearance of the spout, the ramp, and the gray rectangle placed in front of the ramp. As soon as the spout, the ramp, and the gray rectangle appeared, the three objects began to emerge from the spout at half-second intervals and moved down at the same and constant speed. As each object moved down, it disappeared behind the gray rectangle on its way down, made an impact sound while still not visible, turned to the right, moved down the ramp, and finally emerged from behind the gray rectangle and moved off to the right where it came to rest. It took 1.55 s for each object to reach the ramp and make its impact sound. It took another 3.6 s for each object to reach the end of its trajectory at the right of the screen. Once the last object came to rest, all three objects remained visible for 0.5 s, disappeared for 0.75 s, and then the sequence started again and continued to be presented repeatedly either until the infant looked away or until the maximum trial duration was reached (see below).

Procedure. An experimenter observed the infant from a separate control room and, thus, could neither see nor hear the stimuli being presented. Because we used the infant-controlled habituation/test procedure, the infant's looking behavior controlled movie presentation. Whenever the infant looked at the stimulus presentation monitor, the movie began to play and continued to do so either until the infant looked away from the monitor for more than 1 s or until he or she accumulated a total of 48 s looking time. Once either of these two conditions was met, the attention-getter reappeared and remained there until the infant looked back at the monitor. As soon as the infant refixated the attention-getter, the next trial was initiated.

The experiment began with a single pretest trial during which the Winnie the Pooh cartoon was played. The purpose of this trial was to measure the infant's initial level of attention. Once this trial ended, the habituation phase began and continued until the infant reached a predefined habituation criterion. This criterion required that the total duration of looking during the last three habituation trials decline to 50% of the total duration of looking during the first three habituation trials. Once an infant reached the habituation criterion, the habituation phase ended and the next trial initiated the test phase.

Infants were divided into two habituation groups. One group was habituated to the auditory-ABC/visual-ABC movie and the other to the auditory-CAB/visual-CAB movie. Once infants reached the habituation criterion, they were given four test trials. The first of these was a familiar (F) test trial during which the movie that was presented during the habituation phase was presented again. Looking during this trial served as the baseline measure of responsiveness against which responsiveness to the order changes presented in the remaining test trials was assessed. The three remaining test trials were designed to test infants' response to a change in the order of the auditory, the visual, or the audiovisual attributes of order and were designated the A, V, and AV test trials, respectively. The A test trial involved a change in the order of the sounds but not in the order of the objects, the V test trial involved a change in the order of the objects but not in the order of the sounds, and the AV test trial involved a change in the order of sounds and objects. The F test trial was always presented first, whereas the order of the A, V, and AV test trials was counterbalanced according to a Latin square design. Once the last test trial was completed, each infant was given a posttest trial during which the Winnie the Pooh cartoon was presented. This trial served as a check on fatigue effects by measuring the terminal level of attention. Once this trial was completed, the test session ended.

Results and Discussion

An initial analysis was performed to determine whether any infants exhibited spontaneous regression to the mean in the F test trial. Spontaneous regression to the mean was deemed to have occurred for a given infant if his or her looking duration score in the F test trial exceeded the overall mean duration of looking in the F trial by more than 2 *SD*. One infant exhibited spontaneous regression to the mean, and this infant's data were eliminated from any further analyses. Figure 2 shows the results from the habituation and test trials for the remaining 23 infants. The left panel of Figure 2 shows the data from the first three and last three habituation trials and shows that attention declined during the habituation phase (only the first and last three trials are shown because the infant-controlled procedure permits a variable number of habituation trials across infants). To determine whether the decline was statistically reliable and whether it might have differed for the two habituation groups, the data were analyzed by way of a mixed 2 × 6 (Habituation Group × Habituation Trials) repeated measures analysis of variance (ANOVA), with habituation group as the between-subjects factor and habituation trials as the within-subjects factor. Results of this analysis indicated that the habituation trials effect was statistically significant, $F(5, 105) = 20.4$, $p < .001$, and that no other effects were significant. This result indicates that infants exhibited a statistically reliable decrement in responsiveness during the habituation phase and that the nature of this decrement was not affected by the particular sequence presented during habituation.

The right panel of Figure 2 shows the data from the test trials. These data were first analyzed by way of a mixed 2 × 4 (Habituation Group × Test Trial Type) mixed ANOVA, with habituation group as the between-subjects factor and test trial type as a within-subjects factor. Results of this analysis indicated that neither the overall trials effect was significant, $F(3, 63) = 2.28$, $p < .10$, nor any of the other effects. Despite the fact that the overall trials effect was not statistically significant, planned comparisons were theoretically and empirically (Lewkowicz, 2004) justified. Thus, to determine whether infants exhibited statistically reliable response recovery in any of the test trials, separate planned comparison analyses were performed contrasting the duration of looking in each order-change trial, respectively, with the duration of looking in the F test trial. These comparisons indicated that the only test trial in which response recovery reached statistical significance was the AV test trial, $F(1, 21) = 5.26$, $p < .05$. Nonetheless, it is interesting that the average magnitude of response in the A and V test trials was higher than in the F test trial. This raises the possibility that response in these two trials might have reached conventional levels of statistical significance if sample size were increased. It should be noted, however, that the purpose of the current experiment was to faithfully repeat Lewkowicz's (2004) Experiment 2. As a result, it was deemed important that sample size be kept the same as in the original study.

The finding that 3-month-old infants detected the order change in the AV test trial replicates the findings from Lewkowicz's (2004) Experiment 2 and indicates that infants as young as 3 months of age can perceive and discriminate dynamic audiovisual sequences. Second, the fact that 3-month-old infants, like the 4-month-old infants in the Lewkowicz (2004) study, only responded to the audiovisual order change is consistent with the fact that multisensory redundancy is particularly important for infant learning and discrimination in the early months of life (Bahrick, Lickliter, & Flom, 2004). Third, the fact that 3-month-old

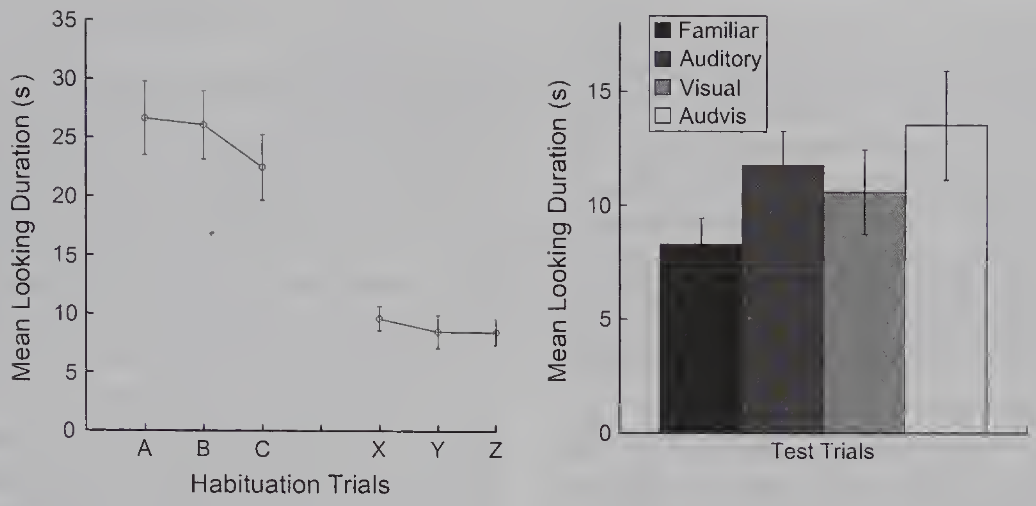

Figure 2. Results from Experiment 1.
Note. The left panel shows the duration of looking during the habituation phase. Because the number of trials to reach the habituation criterion varied across infants, the left panel only depicts the average duration of looking in the first (A, B, and C) and the last three (X, Y, and Z) habituation trials. The right panel shows the duration of looking in the test trials. Error bars indicate the standard error of the mean.

infants perceived and discriminated audiovisual sequences is consistent with previous reports of successful sequence perception in infants of this age (Canfield & Haith, 1991; Gulya et al., 1998) as well as with the fact that temporal- and motion-processing abilities are already present by this age (Lewkowicz, 1989, 2000).

Experiment 2

The contrasting sequences that were presented in Experiment 1 and in Lewkowicz's (2004) study differed in terms of their initial objects and sounds, making it possible that successful discrimination of the contrasting sequences was based on initial element differences. In other words, successful discrimination might have been based on the classic primacy effect rather than on the perception of serial order. It should be noted, however, that this is unlikely for two reasons. First, neither the 3-month-old infants in Experiment 1 nor the 4-month-old infants in Lewkowicz's (2004) study exhibited detection of the visual-only order change despite the fact that it involved the initial object. Second, the infants' failure to respond to the visual-only order change means that their successful detection of the audiovisual order change could not have been based on the visual aspects of this change and, by extension, could not have been based on first object differences either.

Despite the fact that the findings suggest that primacy effects did not contribute to successful discrimination, studies have shown that infants can take advantage of initial sequence element differences (Cornell & Bergstrom, 1983; Merriman et al., 1997). As a result, it is imperative to rule out such primacy effects directly through experimental manipulations of sequence structure. The most convincing way to rule them out is to conduct a direct empirical investigation in which learning of dynamic audiovisual sequences is assessed when the initial elements of contrasting sequences are held constant. As a result, Experiment 2 tested 4-month-old infants' ability to perceive and discriminate dynamic audiovisual sequences whose initial elements were the same.

Method

Participants. Twenty-four 4-month-old infants (*M* age = 19.4 weeks, *SD* = 0.7 weeks; 15 boys and 9 girls) contributed data in this experiment. One additional infant was tested but was not used because of fussing.

Apparatus and stimuli. The apparatus and stimuli in this experiment were identical to those used in Experiment 1 except that here the two contrasting sequences were ABC and ACB.

Procedure. The procedure in this experiment was the same as in Experiment 1 except that here half the infants were habituated to an auditory-ABC/visual-ABC movie and the other half were habituated to an auditory-ACB/visual-ACB movie. Following the habituation phase, each infant was given the four test trials shown in Table 1.

Results and Discussion

Initial examination of the data from the F test trial indicated that two infants exhibited spontaneous regression to the mean, and thus, the data from these infants were excluded from all subsequent analyses. Figure 3 shows the results from the habituation and

Table 1

The Sequences Presented to Each Group in the Habituation and Test Trials in Experiments 2 and 3

Habituation group	Test trials			
	Familiar (F)	Auditory (A)	Visual (V)	Auditory – Visual (AV)
ABC	Auditory-ABC/Visual-ABC	Auditory-ACB/Visual-ABC	Auditory-ABC/Visual-ACB	Auditory-ACB/Visual-ACB
ACB	Auditory-ACB/Visual-ACB	Auditory-ABC/Visual-ACB	Auditory-ACB/Visual-ABC	Auditory-ABC/Visual-ABC

Note. The letters A, B, and C refer to each object and its corresponding impact sound (see the Method section for details).

test trials from the remaining 22 infants. The left panel of Figure 3 shows that infants' looking declined during the habituation phase of the experiment. A mixed 2 × 6 (Habituation Group × Habituation Trials) ANOVA, with habituation group as the between-subjects factor and habituation trials as the within-subjects factor, indicated that the habituation trials effect was statistically significant, $F(5, 100) = 38.23$, $p < .001$, and that no other effects were significant. This result indicates that infants exhibited a statistically reliable decrement in responsiveness during the habituation phase and that the nature of this decrement was not affected by the particular sequence presented during the habituation phase.

The right panel of Figure 3 shows the results of the test trials. As can be seen, infants looked longer in each of the order-change test trials relative to the amount of time they looked in the F test trial. A mixed 2 × 4 (Habituation Group × Test Trial Type) ANOVA, with habituation group as the between-subjects factor and test trial type as a within-subjects factor, indicated that responsiveness differed across the test trials, $F(3, 60) = 3.83$, $p < .025$, and that there were no other significant effects. Planned comparison tests comparing response in each order-change test trial, respectively, versus looking in the F test trial indicated that infants exhibited significant response recovery in the A test trial, $F(1, 20) = 9.67$, $p < .01$; the V test trial, $F(1, 20) = 6.84$, $p < .025$; and the AV test trial, $F(1, 20) = 13.5$, $p < .01$.

The results from this experiment indicate that infants successfully discriminated the sequences despite the fact that the initial sequence element was the same. This finding supports Lewkowicz's (2004) conclusion that initial element differences did not account for 4-month-old infants' successful response. Paradoxically, however, the present findings also showed that in contrast to the findings from Experiments 1 and 2 in Lewkowicz's study, here infants detected unisensory as well as bisensory order changes. The absence of a multisensory redundancy effect is actually consistent with other findings on multisensory redundancy effects in that such effects are assumed to depend, in part, on information complexity (Bahrick et al., 2004). The discriminative task in the current experiment was simpler because infants only had to detect a change in the order of two of three sequence elements, whereas in Lewkowicz's study, infants had to detect a change in the order of three elements.

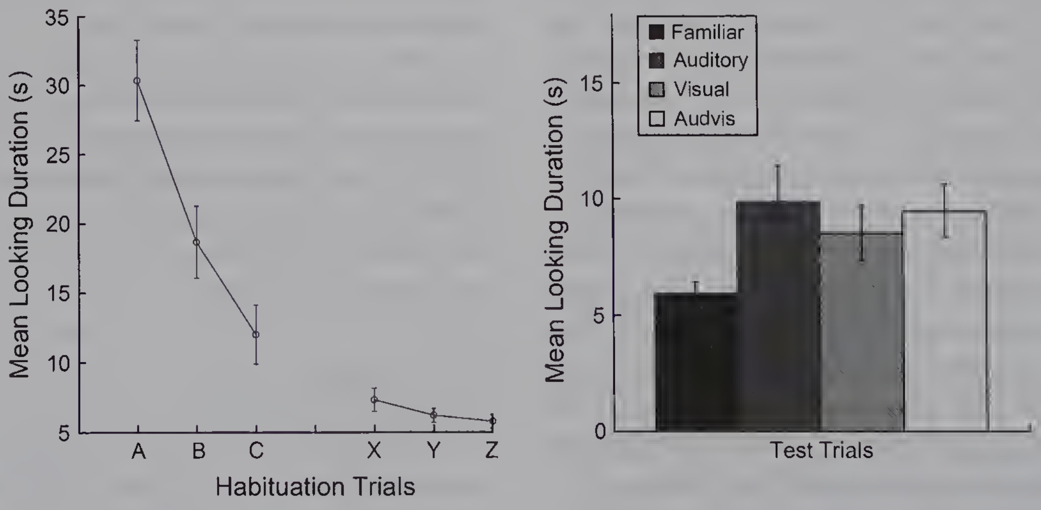

Figure 3. Results from Experiment 2.
Note. The left panel shows the duration of looking during the first three (A, B, and C) and last three (X, Y, and Z) habituation trials, and the right panel shows the duration of looking in the test trials. Error bars indicate the standard error of the mean.

Experiment 3

Several lines of work suggest that motion is likely to contribute in an important way to infant perception and discrimination of dynamic audiovisual sequences. First, findings indicate that infants are sensitive to motion from a very early age (Bertenthal et al., 1987; Dannemiller & Freedland, 1991; Kaufmann et al., 1985; Kaufmann-Hayoz et al., 1986; Shea & Aslin, 1990). Second, evidence indicates that motion plays an important role in object perception in that infants can only perceive the partially visible parts of a moving object as belonging to the same object if the parts move together (Kellman & Spelke, 1983; Kellman et al., 1986). Third, young infants can discriminate between an upright and an upside-down moving point-light display of a walking person on the basis of the correlated motion of the individual lights (Bertenthal, Proffitt, & Cutting, 1984). Fourth, when infants see a moving object, they can anticipate its future position and correctly intercept and catch it (von Hofsten, 1980). Finally, young infants can perceive the temporal relation between a single moving object and its impact sound (Lewkowicz, 1996) and can choose between two moving objects on the basis of their spatiotemporal relationship to an impact sound (Lewkowicz, 1992a).

Despite the possibility that motion is likely to contribute in important ways to infant perception of sequentially structured events, it is currently not known whether it does. This is because, with the exception of the Lewkowicz (2004) study and Experiments 1 and 2 in the current study, all other studies to date on infant sequence perception and learning have presented sounds, looming visual stimuli, or static visual stimuli. Given that young infants are sensitive to motion and that they rely on it for object perception and action, it is interesting to assess the possible contribution of motion to infant perception and learning of dynamic audiovisual sequences. To do so, the present experiment examined 4-month-old infants' response to dynamic sequences whose motion characteristics were reduced (i.e., the objects that loomed and sounded in place).

Method

Participants. Twenty-four 4-month-old infants (*M* age = 19 weeks, *SD* = 0.9 weeks; 15 boys and 9 girls) contributed data in this experiment. An additional 15 infants were tested but were not used because 11 were fussy, 3 were inattentive, and 1 was distracted.

Apparatus and stimuli. The apparatus and stimuli were identical to those used in Experiment 1 except that here all three objects were visible from the beginning to the end of each trial and remained in one place throughout the trial. Figure 1b shows the objects' spatial arrangement. The sequential nature of the event was determined by the objects' looming/sounding behavior. At the start of a trial, the first object gradually increased in size by 20%. When it reached its maximum size, its corresponding auditory stimulus was sounded and the object then returned to its original size. This was followed by the looming of the second and then third object. The looming behavior of each object was continuous in nature, and it took 0.5 s for each object to loom to its maximum size and another 0.5 s to return back to its original size. A 0.5-s interval separated the looming action of each object, and during this interval, all objects remained static and at their original size. Once the last object loomed, all three objects could be seen at their original size for 1 s. This cycle of looming actions was repeated for the duration of the trial.

Procedure. The procedure used in Experiment 1 and the design depicted in Table 1 were used here.

Results and Discussion

Analysis of the F test trial data indicated that two infants exhibited spontaneous regression to the mean in this trial, and as a result, the data from these two infants were eliminated from all subsequent analyses. The habituation and test data from the remaining 22 infants can be seen in Figure 4, and as can be seen in the left panel of Figure 4, looking declined during the habituation phase. A mixed 2 × 6 (Habituation Group × Habituation Trials) ANOVA, with habituation group as the between-subjects factor and habituation trials as the within-subjects factor, indicated that infants exhibited a statistically reliable decrement in responsiveness over trials, $F(5, 100) = 14.12$, $p < .001$, and that the nature of this decrement was not affected by the particular sequence presented during the habituation phase.

The right panel of Figure 4 shows the mean duration of looking in the test trials. A mixed 2 × 4 (Habituation Group × Test Trial Type) ANOVA, with habituation group as the between-subjects factor and test trial type as the within-subjects factor, indicated that responsiveness differed across the test trials, $F(3, 60) = 3.43$, $p < .05$, but that it was not affected by the particular habituation sequence. Planned comparisons indicated that infants exhibited significant response recovery in the A test trial, $F(1, 20) = 6.67$, $p < .025$, but that they did not exhibit response recovery in the other two test trials. As was the case in Experiment 1, here the average magnitude of response in the V and the AV test trials also was higher than in the F test trial, raising the possibility that response in these two trials might have

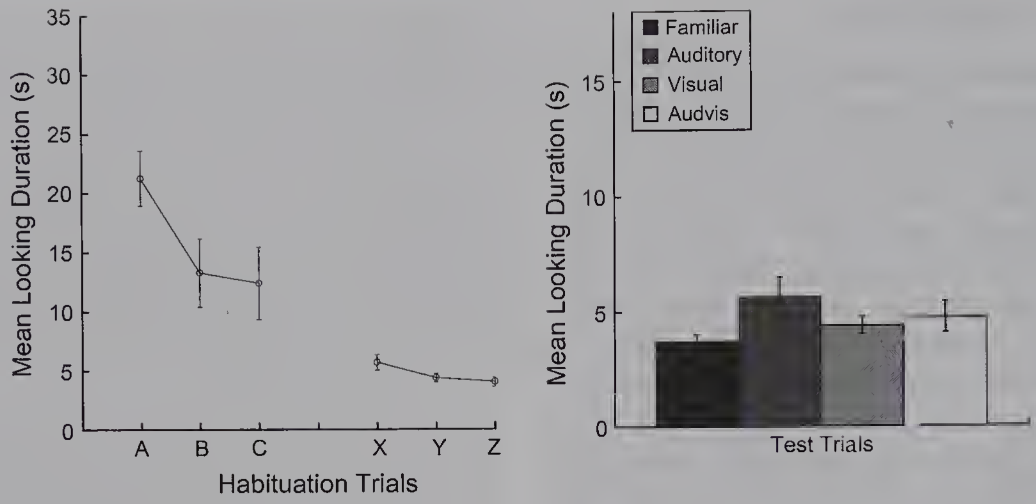

Figure 4. Results from Experiment 3.
Note. The left panel shows the duration of looking during the first three (A, B, and C) and last three (X, Y, and Z) habituation trials, and the right panel shows the duration of looking in the test trials. Error bars indicate the standard error of the mean.

reached conventional levels of statistical significance if sample size were larger. As indicated earlier, however, any legitimate comparison between the outcome in the current experiment and the outcomes in the previous experiments makes it imperative that sample size be held constant.

The results from this experiment indicate that motion plays an important role in infant perception and discrimination of dynamic audiovisual sequences. When motion cues were reduced, infants only responded to the auditory order changes. What makes this finding especially interesting is that the vast majority of studies of sequence learning in human and nonhuman adults (Keele et al., 2003; Terrace, 1993) have used spatially static stimulus arrays and have, nonetheless, obtained successful learning of complex sequences. This suggests that infants' apparent reliance on motion in dynamic audiovisual sequences may serve two functions. First, it may recruit greater attention to the event because moving visual stimuli are known to elicit greater attention than static stimuli (Shaddy & Colombo, 2004; Wilcox & Clayton, 1968). Second, the sequential emergence of the objects at the beginning of each iteration of the event and their subsequent common motion are likely to highlight the event's serial organization. As indicated earlier, infants of this age rely on common motion for object perception (Kellman & Spelke, 1983; Kellman et al., 1986), and thus, it is reasonable to conclude that they also rely on motion for perception of sequential structure.

Experiment 4

In a study of sequence learning with the mobile conjugate reinforcement procedure, Gulya et al. (1998) found that 3-month-old infants could learn to move a series of three mobiles in a particular sequence and that they remembered the order in which they moved them a day later. In a second study, using the same mobile conjugate reinforcement procedure, Gulya et al. (1999) found that 6-month-old infants could learn and remember the order in which they moved a series of five different mobiles and that they remembered this order a day later. Together, these results provide a rough estimate of the limits of sequence learning at these two ages. If these findings are extrapolated to the learning of the kinds of dynamic audiovisual sequences presented in the current study, it is reasonable to predict that 4-month-old infants should be able to perceive, learn, and discriminate sequences consisting of more than three elements.

Although this prediction is reasonable, it is complicated by the fact that young infants' response to the global sequential organization of audiovisually specified sequences can compete with their propensity to attend to local event attributes. That is, Lewkowicz (2004) found that 4-month-old infants do not respond to the overall organization of an audiovisual sequence unless the impact that each object making up a given sequence is blocked from view. To account for this finding, Lewkowicz advanced an attention allocation hypothesis. This hypothesis was based on findings that 4-month-old infants tend to attend to the impact part of moving/sounding objects (Spelke, Born, & Chu, 1983) and on the conclusion that this tendency causes them to miss the overall sequential organization of a dynamic sequence.

If 4-month-old infants' tendency to focus on the audiovisual impact part of an event can affect the allocation of attention to the sequential organization of a dynamic sequence, then other stimulus attributes also might affect it. For example, it is possible that increasing the number of sequence elements may actually shift attention away from the audiovisual impact part of the event and may enable infants to perceive an event's overall sequential organization. This may be because a greater number of sequence elements presented over the same amount of time may make it more difficult for infants to attend to the impact part of each object's motion simply because they go by more rapidly. Thus, although better learning of longer sequences might at first blush appear to be paradoxical, this result actually makes sense when event dynamics are considered. Indeed, this prediction is supported by findings from studies with adults showing that they tend to focus on the global properties of multiple-object scenes rather than on the properties of the individual objects (Navon, 1977, 2003; Pomerantz, 2003). For example, in a scene consisting of multiple gratings, adults perceive the mean orientation of the gratings rather than their individual orientations (Parkes, Lund, Angelucci, Solomon, & Morgan, 2001). Similarly, in a scene consisting of objects differing in size, adults tend to compute the mean size of the overall set of objects (Ariely, 2001; Sussman & Scholl, in press). Thus, the general principle appears to be that the greater the amount of information, the more attention is allocated to global stimulus features. This kind of global precedence effect also has been found in infants. In particular, studies have shown that 4-month-old but not younger infants tend to focus more on global than on local stimulus attributes (Colombo, Mitchell, Coldren, & Freeseman, 1991; Freeseman, Colombo, & Coldren, 1993). As a result, it is reasonable to conclude that by 4 months of age infants might attend more to the overall organization of a sequence when it consists of a greater number of elements and, in the process, may exhibit facilitation of learning.

If it is found that learning of the sequential organization of a longer dynamic audiovisual sequence is better than the learning of a shorter one, then this would suggest that, up to some limit the relationship between sequence complexity and learning is nonlinear in early infancy. Such a nonlinear effect is actually consistent with general principles of infant information processing (Cohen, Chaput, & Cashon, 2002). According to these principles, infants attempt to process events in terms of their highest information level possible and only drop to a lower information level when the processing system gets overloaded. In the case of dynamic audiovisual sequences, infants' first tendency may be to attempt to apprehend the sequential organization of the event. If, on the one hand, the event consists of a low number of objects moving relatively slowly, infants may be perceptually captured by the audiovisual impacts made by each object and, as a result, may drop to a lower level of processing. If, on the other hand, the event consists of a larger number of objects, then the global precedence effect may redirect their attention to the event's global attributes and they may respond to the event's overall sequential organization.

The purpose of Experiment 4 was to test the attention allocation hypothesis and the prediction that presentation of a longer sequence over the same amount of time may actually facilitate perception, learning, and discrimination. To do so, 4-month-old infants' response to four-element dynamic audiovisual sequences was investigated in this experiment. In addition, the purpose of Experiment 4 was to provide a strong test of the attention allocation hypothesis. This was done by allowing infants to see the impact part of the event. By doing so, it was possible to determine how the tendency to focus on the local (i.e., impact) part of the event and the competing tendency to attend to the global organization of the sequence would affect response. If the infants continue to focus on the event's local attributes, then, like the infants in Experiment 1 in Lewkowicz's (2004) study, they should only respond to the bisensory order change. In contrast, if they now shift their attention to the event's global attributes, then they should exhibit more robust evidence of the detection of serial order changes and, thus, should respond to the unisensory order changes as well.

Method

Participants. Twenty-four 4-month-old infants (*M* age = 19 weeks, *SD* = 0.75 weeks; 10 boys and 14 girls) contributed data in this experiment. One additional infant was tested but was not included because of fussing.

Apparatus and stimuli. All aspects of this experiment were the same as those of Experiment 1 with two important exceptions. First, the sequences consisted of four distinct objects and sounds. Three of the objects and sounds were identical to those presented in Experiment 1. The new fourth object resembled a star that had an orange interior and purple apices and was accompanied by a sound corresponding to a blip.wav file. Second, here the gray rectangle shown in Figure 1a was still visible except that now it was placed behind the objects' motion path. As a result, infants could now see the objects along their entire motion trajectory and, thus, could see and hear the impact that each object made as it changed its direction of motion.

Procedure. As in Experiment 1, each movie began with the appearance of the spout, ramp, and the gray rectangle. Thirty milliseconds later, the first object emerged from the spout and moved down. The next three objects then emerged 0.53, 1.03, and 1.53 s following the emergence of the first object, respectively. All four objects moved down at the same and constant speed and contacted the ramp 1.83, 2.33, 2.83, and 3.33 s following their emergence from the spout, respectively. Following contact with the ramp, the objects turned to the right, slid down the ramp, and came to a stop 4.53, 4.78, 5.15, and 5.43 s following their emergence from the spout, respectively. Once the last object came to a stop, all four objects remained visible and stationary for 0.5 s. The objects then disappeared, and 0.6 s later, the event started again and continued to be repeated for the duration of the trial. To ensure that infants were not basing their discrimination on initial element differences, the initial element of the contrasting sequences was kept constant. The overall design of this experiment can be seen in Table 2.

Results and Discussion

Inspection of the F test trial data indicated that 1 infant exhibited spontaneous regression to the mean in this trial; therefore, this infant's data were eliminated from all subsequent analyses. The habituation and test data from the remaining 23 infants can be seen in Figure 5, and as can be seen in the left panel of Figure 5, looking declined during the habituation phase. A mixed 2 × 6 (Habituation Group × Habituation Trials) ANOVA, with habituation group as the between-subjects factor and habituation trials as the within-subjects factor, indicated that infants exhibited a statistically reliable decrement in looking during the habituation phase, $F(5, 105) = 17.3, p < .001$, and that the nature of this decrement was not affected by the particular sequence presented during this phase.

The right panel of Figure 5 shows the mean duration of looking in the test trials. A mixed 2 × 4 (Habituation Group × Test Trial Type) ANOVA, with habituation group as the between-subjects factor and test trial type as the within-subjects factor, indicated that responsiveness differed across the test trials, $F(3, 63) = 2.88, p < .05$, but that it was not affected by the particular habituation sequence. Planned comparison tests indicated that infants exhibited significant response recovery in the A test trial, $F(1, 21) = 6.44, p < .025$; the V test trial, $F(1, 21) = 4.84, p < .05$; and the AV test trial, $F(1, 21) = 11.5, p < .01$.

The outcome of this experiment was consistent with the attention allocation hypothesis and with the prediction that infants may exhibit more robust detection of serial order changes. This was evident in the fact that infants successfully detected the unisensory as well as bisensory order changes. The finding that infants detected all three types of order changes despite the fact that they had access to the audiovisual impact part of the event provides strong support for the assumptions underlying the attention allocation hypothesis and its prediction that increasing the number of sequence elements should shift attention to the overall serial organization of the sequences. Had infants not shifted their attention to the event's global sequential organization, they would not have detected the unisensory order changes. Moreover, the finding that infants exhibited successful sequence perception and discrimination despite the fact that the initial elements of the contrasting sequences did not differ provides further proof that they perceived the events' global sequential organization and that primacy effects did not play a role in responsiveness.

General Discussion

The results from the current study replicate as well as extend the findings from Lewkowicz's (2004) study of infant perception and discrimination of dynamic audiovisual sequences. They do so in a number of ways. First, they show that infants as young as 3

Table 2
The Sequences Presented to Each Group in the Habituation and Test Trials in Experiment 4

Habituation group	Test trials Familiar (F)	 Auditory (A)	 Visual (V)	 Auditory – Visual (AV)
ABCD	Auditory-ABCD/ Visual-ABCD	Auditory-ADBC/ Visual-ABCD	Auditory-ABCD/ Visual-ADBC	Auditory-ADBC/ Visual-ADBC
ADBC	Auditory-ADBC/ Visual-ADBC	Auditory-ABCD/ Visual-ADBC	Auditory-ADBC/ Visual-ABCD	Auditory-ABCD/ Visual-ABCD

Note. The letters A, B, C, and D designate each object and its corresponding impact sound (see the Method section for details).

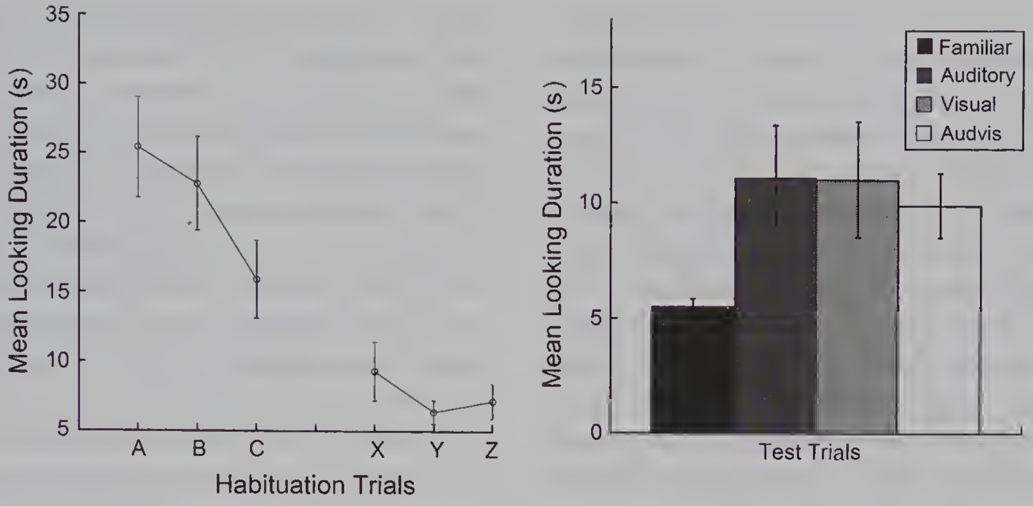

Figure 5. Results from Experiment 4.
Note. The left panel shows the duration of looking during the first three (A, B, and C) and last three (X, Y, and Z) habituation trials, and the right panel shows the duration of looking in the test trials. Error bars indicate the standard error of the mean.

months of age can perceive and discriminate three-element dynamic audiovisual sequences and that they, like 4-month-old infants, rely on multisensory redundancy for successful perception and discrimination (Experiment 1). Second, they show that 4-month-old infants can discriminate between contrasting dynamic audiovisual sequences even when their initial elements are held constant (Experiments 2 and 4). This indicates that primacy effects do not account for infants' successful detection of sequence differences. Third, they show that motion plays an important role in perception and discrimination of dynamic audiovisual sequences in that infants exhibited less robust responsiveness to audiovisual sequences consisting of looming rather than moving objects (Experiment 3). Finally, the current results show that 4-month-old infants can perceive and discriminate longer sequences in that they not only perceived and discriminated four-element sequences but also exhibited more robust responsiveness to such sequences (Experiment 4).

The finding that 3-month-old infants relied on multisensory redundancy to encode and detect serial order is consistent with evidence from human infant (Bahrick & Lickliter, 2000; Bahrick et al., 2004; Lewkowicz & Kraebel, 2004), human adult (Hershenson, 1962; Stein & Meredith, 1993; Summerfield, 1979), and animal adult (Partan & Marler, 1999; Rowe, 1999) studies indicating that attention, learning, and discrimination are substantially better when events are specified redundantly in multiple sensory modalities. At the same time, however, the findings from the other experiments that 4-month-old infants detected serial order changes in less complex three-element sequences (Experiment 2) and in more complex four-element sequences (Experiment 4) regardless of whether they were redundantly specified indicate that the value of multisensory redundancy in early infancy is modulated by the particular nature of the information to be processed and by task difficulty (Bahrick et al., 2004). That is, when the perceptual task of encoding serial order is made difficult by presenting fewer sequence elements, infants tend to rely on multisensory redundancy to extract the serial order information. In contrast, when the perceptual task is made easier by presenting a larger number of sequence elements and thus shifting infants' attention to the global event attributes, infants no longer need to rely on multisensory redundancy for perceiving and encoding the event's sequential organization.

The results from Experiments 2 and 4 clearly demonstrate that primacy effects do not account for young infants' response to dynamic audiovisual sequences. In particular, they indicate that infants do not base their detection of serial order changes on initial element differences. As a result, they support Lewkowicz's (2004) conclusion that the pattern of findings in that study did not reflect primacy effects.

The finding in Experiment 3 that infants only perceived the auditory order attributes of sequences composed of looming/sounding objects shows clearly that motion contributes to infant perception of sequential structure. Most likely, infants' attention is captured and/or recruited by moving objects to such an extent that it causes them to focus on the objects' serial ordering. Indeed, this beneficial effect of motion on perception has been found in a number of other studies of infant response to multisensory events. For example, when infants are given a choice between two static visual stimuli and a sound that corresponds to one of them in terms of onset and offset synchrony and temporal rate, they do not make intersensory matches (Lewkowicz, 1985). Similarly, when infants are habituated to a spatially static visual stimulus (i.e., a flashing checkerboard) and a pulsing tone, they respond primarily to the auditory information (Lewkowicz, 1988a, 1988b). In contrast, when infants are habituated to a bouncing visual stimulus and an accompanying impact sound, they respond to changes in the rate of visual and auditory information (Lewkowicz, 1992b) as well as to the temporal synchrony relation between these two sources of information (Lewkowicz, 1996). Likewise, when infants are given a choice between two moving visual stimuli and a sound that corresponds to the impact that one of these visual stimuli makes, they detect the temporal relationship between the visible and the audible impacts (Lewkowicz, 1992a). In other words, infants can flexibly change how much attention they devote to a particular event depending on the particular type of information provided. When objects move, infants devote substantial attentional resources to motion-related information and, in the process, learn to extract specific spatiotemporal information that they can then use for relating the objects' behaviors to what they are hearing. Perhaps the most dramatic illustration of this fact is evidence that infants as young as 6 months of age can take advantage of specific spatiotemporal relations between ambiguously moving objects and concurrently presented sounds and by doing so end up perceiving audiovisual illusions (Scheier et al., 2003).

The results from Experiment 4 extend the findings from Experiments 1–3 and the findings from Lewkowicz's (2004) study by demonstrating that 4-month-old infants can perceive longer, four-element dynamic audiovisual sequences. One particularly interesting aspect of the results from Experiment 4 is that infants exhibited robust detection of serial order changes despite the fact that the impact part of the event was visible. This contrasts with infants' failure to detect any serial order changes in their response to three-element sequences in Lewkowicz's (2004) Experiment 1 where the impact part of the event also was visible. At first blush, the results from Experiment 4 appear to be paradoxical. When considered in the context of the attention allocation hypothesis, however, they actually make a good deal of sense. According to this hypothesis, perception and discrimination of dynamic audiovisual sequences depend on the particular nature of sequences and the flexible allocation of attention to different aspects of such sequences. The results from the current study suggest that young infants' response to dynamic audiovisual sequences of different lengths/complexity depends on two competing perceptual processes. One compels young infants to attend to the event's local attributes (i.e., the audiovisual impact) and the other compels them to attend to the event's global attributes (i.e., the overall serial organization). Which one dominates processing depends on the length of the sequence. When the sequence consists of fewer elements, infants attend to the local attributes and, thus, find it more difficult to detect serial order changes. In contrast, when the sequence consists of more elements, infants attend to the global attributes and, thus, find it easier to detect serial order changes.

Although the attention allocation hypothesis and its a priori predictions received strong empirical support in the current study, future studies might examine eye movements to test the hypothesis even more directly. The straightforward prediction arising from the hypothesis is that in the case of three-element sequences whose audiovisual impact is not blocked from view, 4-month-old infants should fix their eye gaze more on the impact part of the event and, as a result, should engage in less tracking of the various objects. In contrast, in the case of four-element sequences whose audiovisual impact is also not blocked from view, 4-month-olds should track the motion of the objects more and, as a result, should fix their gaze less on the impact part of the event.

The current findings, together with those from Lewkowicz's (2004) study, clearly indicate that young infants are sensitive to information specifying the serial organization of dynamic audiovisual sequences. At the same time, however, this set of findings does not permit any firm conclusions regarding the specific type of information that mediated successful discrimination of serial order differences. This is because the contrasting sequences in the current and in Lewkowicz's (2004) study differed in terms of adjacent as well as ordinal position relations. A recently completed study in the author's laboratory (Lewkowicz & Berent, 2008) helps shed some light on what particular information infants respond to when processing the types of dynamic audiovisual sequences presented here. In this study, we habituated 4-month-old infants to several different four-element sequences consisting of the same types of objects and impact sounds presented here. Three of these objects and their sounds were presented in different ordinal positions across different habituation trials, whereas one, the target element, was presented in an invariant ordinal position. Results showed that infants detected a change in the ordinal position of the target element when that change occurred in the context of familiar sequence elements but that they did not detect the change when it occurred in the context of three novel sequence elements. Moreover, results indicated that infants' response to ordinal position differences in the familiar context was based on their detection of statistical relations (i.e., transitional probability relations among adjacent sequence elements) and not on their detection of ordinal position information. Based on these results, the most conservative interpretation of the data from the current study is that infants' responsiveness was probably based on their detection of statistical relations and not of ordinal relations.

Overall, the findings from the current study indicate that the ability to perceive dynamic audiovisual sequences emerges early in human development. This ability surely provides the essential developmental foundation for the subsequent emergence of higher level perceptual and cognitive skills. For example, it is known that 7-month-old infants can extract the syntactic structure of a linguistic utterance (Marcus et al., 1999), 8-month-old infants can produce a series of correctly sequenced actions to achieve a goal (Piaget, 1952), 11-month-olds can parse the temporal structure of ongoing behaviors along boundaries related to the initiation and completion of intentions (Baldwin, Baird, Saylor, & Clark, 2001), and 12-month-old infants understand that actions that occur in a sequence can imply an overarching goal (Woodward & Sommerville, 2000). Successful performance in all these tasks depends on infants' ability to perceive the underlying serial ordering of sequence components. The fact that the kinds of sequence perception skills investigated here are already present by 3 months of age suggests that the perceptual foundation for the development of the higher level skills emerges early in life.

The challenge for future studies is to determine when particular sequence perception, learning, and discrimination skills emerge; how they change and improve with development; and how they contribute to the development of higher level perceptual and cognitive skills. Currently, it is not clear what particular sequence perception skills emerge at what point in development and why they emerge at that particular time. Nelson (1986) and Greenfield (1991) have proposed that humans are endowed with a sensitivity to sequential structure at birth and that this sensitivity provides the developmental basis for the emergence of higher level event representation and comprehension skills. Although the finding that infants as young as 3 months of age can perceive and discriminate dynamic audiovisual sequences is generally consistent with these theoretical views, it does not mean that the ability to perceive the types of sequential event structures presented here is present at birth. First, motion perception is initially relatively poor, begins to emerge at 1 month of age, and continues to improve over the next several months. As a result, it is unlikely that newborn infants would be able to extract serial order information from an array of several moving objects. Second, despite the fact that infants come into this world with a general sensitivity to temporal information (Nazzi, Bertoncini, & Mehler, 1998), this sensitivity is relatively poor initially and improves over the 1st year of life (Morrongiello, Kulig, & Clifton, 1984; Trehub, Schneider, & Henderson, 1995). Finally, experience with moving/sounding objects during the first months of life is likely to contribute in important ways to the eventual acquisition of more sophisticated perceptual skills and, by extension, to the acquisition of sequence perception and learning skills.

The foregoing considerations suggest one reasonable preliminary theoretical model of the emergence of sequence perception skills. According to this model, an initial general sensitivity to temporal information provides infants with the first perceptual tools to begin to discover the hidden temporal structure inherent in multisensory events. As infants begin to perceptually differentiate this structure, they first discover the relatively simple statistical relations linking adjacent sequence elements. With further perceptual experience and differentiation, infants progressively discover increasingly more complex sequential relations. Thus, according to this scenario, following the discovery of statistical relations, they next discover that the elements of a sequence can be related to one another in terms of their ordinal position. Then, they discover that sequence elements can be related in a rule-bound manner (i.e., in terms of syntactic-like rules). Finally, they discover that sequence elements can be related in terms of hierarchical sequential relations (as in recursion). One assumption underlying this model is that the discovery of each type of sequential relation emerges from the earlier acquisition of the previous and presumably less complex sequential relation. Although this developmental model is admittedly speculative, it is consistent with currently available evidence on sequence perception and learning in infancy. Moreover, this model is developmental in nature and specifies the particular types of information that infants are able to perceive as they continue to improve their sequence perception abilities. Needless to say, it is up to future studies to determine whether the current model offers a reasonable account of the development of sequence perception, learning, and discrimination skills in infancy and whether it provides insights into the developmental basis for the acquisition of higher level cognitive skills during infancy and beyond.

Longitudinal Analysis of Intrinsic Motivation and Competence Beliefs: Is There a Relation Over Time?

Birgit Spinath and Ricarda Steinmayr
University of Heidelberg

The present study explored whether competence beliefs and intrinsic motivation for different school domains show reciprocal effects over time. A sample of 670 German elementary school pupils ($M = 8.8$ years, $SD = 0.51$) was followed over 1 year. At 4 measurement occasions, children completed self-reports on their intrinsic motivation and competence beliefs for math, German, and school in general. Latent growth models revealed that intrinsic motivation and competence beliefs decreased over time. Comparing correlational and cross-lagged structural equation models yielded only weak evidence for cross-lagged influences between the 2 constructs. Results suggest that the developmental curves of competence beliefs and intrinsic motivation might be less inextricably interwoven than frequently assumed.

Maybe more than anything else, to be well equipped for lifelong learning, individuals need high, sustainable motivation to learn. In sharp contrast to this need for lifelong learning stands the observation that important prerequisites for learning, such as intrinsic motivation for school-related learning, diminish both during an individual's development (e.g., Gottfried, 1990; Gottfried, Fleming, & Gottfried, 2001; Spinath & Spinath, 2005b) and from one generation of pupils to the next (Cocodia et al., 2003; Howard, 2001). Therefore, there is a vital interest among researchers and educators to understand why intrinsic motivation for learning weakens and to find ways to preserve or reactivate the initially high intrinsic motivation for learning among young children. The present study investigated whether the well-established decline of competence beliefs and intrinsic motivation for learning during the 1st school years (i.e., in 6- to 10-year-old children) are not only parallel developments but mutually influencing each other. Specifically, we investigated the assumption that intrinsic motivation to learn declines as a consequence of children developing more realistic and therefore less positive ability self-concepts.

We chose this particular age for investigation because of the changes in children's concepts about ability between 6 and 10 years of age (e.g., Nicholls, 1978; Nicholls & Miller, 1984) and the co-occurring changes in the school environment (i.e., increasingly normative feedback). These developments should make potential reciprocal effects between competence beliefs and intrinsic motivation especially well observable. As it is common practice in most German elementary schools, children received their first grades during the investigated time. Usually, up until third grade only verbal evaluations are given that allow for less social comparisons among pupils. Therefore, if there is any relation between competence beliefs and intrinsic values over time, it should be very pronounced at this phase during school trajectory.

This study sets out to overcome some of the methodological short comings of prior research on related issues, in that its design follows established guidelines for investigating reciprocal effects in general (Marsh, Byrne, & Yeung, 1999) and relations between competence beliefs and intrinsic values specifically (Eccles, 2005). We realized a 1-year longitudinal assessment of competence beliefs and intrinsic motivation in three domains (math, German, and school in general) with four measurement occasions. Using structural equation models, it was tested whether cross-lagged paths between competence beliefs and intrinsic motivation at different measurement occasions were necessary to describe the data adequately (cross-lagged models) or whether more parsimonious correlational models provided equally good descriptions. Only if competence beliefs and intrinsic values were to show substantial cross-relation over time, would there be reason to assume that intrinsic motivation might drop as a consequence of less positive ability self-perceptions.

Defining the Concepts of Intrinsic Motivation and Competence Beliefs

The concept of intrinsic motivation plays a vital role in different motivation theories (e.g., Deci & Ryan, 1985; Wigfield & Eccles, 2000). In the present article, we focus on the concept of intrinsic task values as included in the expectance-value theory of motivation by Eccles and her associates (cf. Wigfield & Eccles, 2000). Intrinsic task values denote the degree of positive affective evaluation of an activity, that is, liking and enjoyment, for reasons that lie within the activity itself rather than its consequences. Although intrinsic task values are not the only reason for learning, task enjoyment can be considered as the most desirable state for learners because learning comes as a by-product of engaging in a pleasurable activity. Moreover, it has been shown that intrinsic task values are the most important reasons for task engagement in elementary school children who do not yet differentiate other task values such as utility or importance (e.g., Eccles, Wigfield, Harold, & Blumenfeld, 1993; Wigfield & Eccles, 1992).

The second motivational construct we focus on in the present work is the concept of competence beliefs. In the expectancy-value model by Eccles and her colleagues (Eccles et al., 1983; Wigfield & Eccles, 2000), task values and expectations of future success are the two most proximal determinants of achievement-related choices. Expectancies for future success are usually operationalized by domain-specific ability self-perceptions. In school contexts, students are asked how good they think they are at certain tasks or in certain domains (e.g., Wigfield et al., 1997). It has been shown that children distinguish very early between expectancies and values for certain school domains (e.g., Eccles et al., 1993), so that in elementary school, children's ability self-perceptions and intrinsic values are distinct characteristics.

Why Should Intrinsic Motivation and Competence Beliefs Be Related?

The assumption that intrinsic motivation for learning and perceptions of one's competences are related is derived from both empirical observations and motivation theories. Experienced teachers as well as developmental researchers observe that not only intrinsic motivation for learning declines from elementary school age through adolescence but that the same is true for children's competence beliefs (e.g., Bouffard, Marcoux, Vezeau, & Bordeleau, 2003; Gottfried et al., 2001; Spinath & Spinath, 2005b; Wigfield et al., 1997). Whereas preschool children view their own competences in an overoptimistic way (cf. Stipek & MacIver, 1989), older children perceive themselves more realistically and sometimes even develop overpessimistic self-perceptions (e.g., R. S. Newman, 1984; Spinath & Spinath, 2005a; Stipek & Daniels, 1988; Wigfield et al., 1997). This parallel decline nourishes the plausible assumption that children's competence beliefs and their intrinsic values are causally linked: When children believe less in their competences, they are bound to lose their enjoyment of task engagement. Yet, whether the decline of competence beliefs and intrinsic motivation at this specific age are actually mutually influencing or only parallel but independent developments still needs to be discovered.

Reasons for declining competence beliefs. What are the reasons for children between 6 and 10 years old to perceive their competencies more realistically and therefore, in most cases, less positively? During this time, children become increasingly able to differentiate between effort and ability as causes of achievement outcomes and attain an understanding of ability as a capacity of the person (Nicholls, 1978; Nicholls & Miller, 1984). Once children attain this understanding about ability, they are more likely to use social comparison information to evaluate their own ability (e.g., Ruble, Boggiano, Feldman, & Loebl, 1980; Ruble, Parsons, & Ross, 1976). In addition, children learn to differentiate more strongly between ability domains such as physical, social, and academic abilities (Harter, 1982). Taken together, these developments contribute to children's growing competence to perceive their own ability accurately, that is, more in line with valid criteria of their actual ability (e.g., Harter, 1982; R. S. Newman, 1984; Spinath & Spinath, 2005a). Coming from overoptimistic self-perceptions, for most children, these changes mean a downward correction of their ability self-perceptions.

It is probably no coincidence that in most school systems, children are confronted with more social comparisons and normative feedback at a time when they develop a normative concept of ability. For example, in most German schools, children receive their first grades when they are about 9 years old, that is, in Grade 3. Up to that point, they would have had only verbal evaluations that are meant to focus on children's individual development rather than social comparisons among pupils. Thus, the age group of 9-year-olds that we investigated is at a special phase in their school trajectory where normative evaluations of competence become extremely salient (e.g., Eccles et al., 1993). We reasoned that if there are mutual influences between competence beliefs and intrinsic values over time, they should be very pronounced at this phase during school trajectory.

Theoretical grounds on which to assume a causal link between ability beliefs and intrinsic motivation. A theoretical background for the assumption that intrinsic motivation depends on competence perceptions is provided by White's (1959) theorizing about effectance motivation. According to White, individuals have an innate desire to feel competent. This effectance motivation drives individuals to engage in tasks in which mastery is at stake. Tasks that generate feelings of efficacy should be experienced as enjoyable or intrinsically rewarding and, as a by-product, prompt learning. Thus, in White's theory, feeling competent and being intrinsically motivated are the same. One has to note, however, that White's concept of feelings of efficacy or competence is not the same as the ability beliefs we focus on in the present investigation. Competence beliefs as operationalized by ability self-perceptions are cognitive representations about the level of ability one perceives to have. Nevertheless, White's theorizing provided the basis on which many motivation researchers grounded the assumption of a causal relation between competence beliefs and intrinsic motivation.

Building up on White's (1959) more general theorizing, Harter (1981a) refined and extended White's assumptions in an effort to provide testable hypotheses under a developmental perspective on competence beliefs. Harter distinguishes between competence beliefs as cognitive representations of the level of one's ability and motivational orientations (i.e., intrinsic and extrinsic motivation). In Harter's (1981a, p. 38) effectance motivation model, intrinsic pleasure in task engagement is a function of successful mastery of challenging tasks and perceived competence. Conversely, failure and perceived lack of competence should result in anxiety in mastery situations, an emotion known to be incompatible with enjoyable feelings. In postulating this sequential process, Harter disentangles perceived competence and motivational orientation and predicts that higher levels of perceived competence entail higher levels of intrinsic motivation. Some of the most prolific modern motivation theories share the assumption that more positive ability self-perceptions should generate more intrinsic motivation for a given task (e.g., Deci & Ryan, 1985; Wigfield & Eccles, 2000).

It is important to note that all theoretical reasoning about the relation between competence beliefs and intrinsic motivation assumes that prior competence beliefs influence subsequent intrinsic motivation. Although one could argue that prior intrinsic motivation could also have an influence on subsequent competence beliefs, there is no elaborated theoretical background making a strong point for such directional effects. Therefore, in the present investigation, we focus on the question whether there is evidence that competence beliefs might influence intrinsic motivation.

Why could competence beliefs and intrinsic motivation develop in parallel but without mutual influences? Although there is strong theoretical reasoning on which to ground the assumption that competence beliefs are important for intrinsic motivation, it is also worthwhile to look for theoretical reasons why such a link might not exist or be only weak. One could argue that it is not the absolute level of self-perceived ability that is important for the degree of task enjoyment but other kinds of ability-related self-perceptions. One line of reasoning can be drawn from Harter's (1981a) specifications to White's (1959) theory of effectance motivation. This specification concerns the relation between success and feelings of efficacy. Harter pointed out that feelings of efficacy, and therefore intrinsic motivation for task engagement, are maximized not by the mere quantity of success but by succeeding at optimally challenging tasks. In other words, intrinsic motivation should depend on an optimal fit between task difficulty and own competence. Such an optimal fit can be given at different levels of competence, so that not only the most competent individuals experience intrinsic motivation. Therefore, the degree of intrinsic motivation might not so much depend on the absolute level of normatively based ability perceptions but rather on perceiving oneself as successful at tasks that fit the level of one's competence. If this was true, we would expect no or only weak indications of normatively based ability self-perceptions influencing intrinsic motivation.

Taken together, developmentally focused motivational theories often assume a causal influence of competence beliefs on intrinsic motivation. Because competence beliefs undergo specific changes in the early school years that lead most children to less positive ability self-perception, declines in intrinsic motivation seem to be an inevitable consequence from this point of view. If, however, it could be shown that the development of intrinsic motivation is not or only weakly dependent on the development of competence beliefs, then the trajectories of the two might be disentangled by means of interventions.

Methodological Guidelines for Investigating Reciprocal Effects Over Time

After theorizing about the nature of the relation between competence beliefs and intrinsic motivation, we take a look at the empirical literature. There is ample evidence on the positive correlation among intrinsic motivation and competence beliefs within domains (e.g., Deci & Ryan, 1985; Harter, 1981b; Wigfield, 1994; Wigfield et al., 1997). Most of these studies are cross-sectional and correlational and allow no conclusions about a potentially causal relationship between the two constructs over time. In order to investigate whether prior competence beliefs might be influential for subsequent intrinsic motivation, longitudinal designs are needed.

In an effort to develop stronger methodological approaches to test for reciprocal effects between concepts in longitudinal designs, Marsh (1990) and Marsh et al. (1999, p. 156) provided valuable guidelines. These authors state that in order to detect causal relations, first, two constructs need to be shown to have a significant statistical relation (i.e., substantial path coefficients in structural equation models). Second, clear time precedence needs to be established in longitudinal studies with at least two and preferably more measurement occasions. Third, theoretical models must be tested by means of statistical techniques such as structural equation modeling (SEM) with all latent constructs inferred on the basis of multiple indicators. The most adequate description of the empirical data is derived by fitting the data to different theoretically plausible models among which to choose the best fitting one.

The present study realizes all these recommendations to examine the relationship between competence beliefs and intrinsic motivation. We are not aware of another study that conducted a 1-year longitudinal assessment of competence beliefs and intrinsic motivation in three domains (math, German, and school in general) with four measurement occasions. The two constructs were measured on a latent basis by three manifest indicators each. This design allows for comparing different theoretical models that differ in whether or not they assume causal relations between competence beliefs and intrinsic motivation. Specifically, it was tested whether cross-lagged paths between competence beliefs and intrinsic motivation at different measurement occasions were necessary to describe the data adequately (cross-lagged models) or whether more parsimonious correlational models provided equally good descriptions. According to a basic scientific principle, in the case of two competing models, which describe a phenomenon equally well, the more parsimonious model or theory should be preferred over the more complex one. Although the preference of the more parsimonious model in the case of an equal fit to the data does not rule out the existence of cross-lagged effects, such effects would be rather weak.

Of course, longitudinal designs cannot provide unequivocal evidence for causal influences. They are, however, very useful to test for necessary prerequisites of causal influences and give an impression of how strong such influences might be. Concerning the present investigation, this means that in case of no cross-lagged relations between prior competence beliefs and later intrinsic motivation, there is no basis for further investigating causal influences. Furthermore, the present design provides an estimation of the upper limit of the strength of potential causal influences. If there are only weak relations over time between competence beliefs and intrinsic motivation, this indicates that causal influences between the two might at best be weak.

Previous Longitudinal Studies Investigating the Link Between Intrinsic Motivation and Competence Beliefs

We identified five longitudinal studies investigating the link between intrinsic values for school-related learning and competence beliefs over time. Not all these studies followed the guidelines by Marsh and colleagues.

One of the most extensive studies concerning the link between intrinsic task values and competence beliefs (Jacobs, Lanza, Osgood, Eccles, & Wigfield, 2002) relied on the sample of the Michigan Childhood and Beyond Longitudinal Project initiated by Eccles and her associates. The development of children's self-perceptions, task values, and activity choices was investigated from Grade 1 to Grade 12. Hierarchical linear modeling was used to analyze the development of task values and self-concepts. When the development in task values was controlled for competence beliefs, the linear trends of the developmental curves were reduced in all investigated domains. Even though these results document the relation between ability beliefs and task values over time, they cannot be interpreted causally: Neither was the change in task values controlled for prior task values nor can the direction of a potential influence be clarified.

Nurmi and Aunola (2005) assessed intrinsic task values and ability self-beliefs in 6- to 7-year-olds at two measurement occasions during Grade 1 and Grade 2. By means of cluster-by-states analysis for longitudinal data, these authors found no association between academic self-concept and mathematical or reading task values when controlling for prior task values. The fact that this study found no evidence for potentially causal influences between competence beliefs and intrinsic values might be due to the young age of the investigated children who had probably not yet attained a concept of ability as a capacity of the person (Nicholls, 1978; Nicholls & Miller, 1984).

Whereas the two studies cited above did not use SEM, the following three studies used methodological approaches partly in line with the recommendations by Marsh and his colleagues. Skaalvik and Valas (1999) investigated mathematical and verbal ability self-concepts and motivation in three age groups (third, sixth, and eighth graders) over two school years with two measurement occasions. Motivation was measured by items reflecting either interest or the will to invest in a certain subject. Six SEMs were tested (two for each domain in each grade), resulting in little evidence for directional effects between competence beliefs and motivation. Specifically, with one exception, none of the cross-paths reached statistical significance (the path from motivation at Measurement Occasion 1 to ability self-concept at Measurement Occasion 2 in math was significant).

One feature of this study that might have impeded finding reciprocal effects is that the measurement occasions were rather far apart. The confirmation of directional effects might depend on the right time lag between measurement occasions. It has been argued that intervals between measurements should not be too long (e.g., Eccles, 2005) to prevent potential reciprocal influences from being masked by other processes. On the other hand, observations need to cover a sufficiently long time for effects to manifest themselves. To investigate both short-term and long-term reciprocal effects, the present investigation employed 3-month intervals and additionally tests for cumulative effects over the timespan of 1 year.

Another study that failed to find evidence for reciprocal effects between intrinsic motivation and competence beliefs is reported by Spinath and Spinath (2005b). Five cohorts of elementary school children ranging from Grade 1 to Grade 4 participated in the study. The cohorts were followed over a period of 2 years and children gave self-reports on their motivation (i.e., intrinsic values and learning goals) and their competence beliefs for school in general every 6 months. Data were analyzed by comparing a more complex reciprocal effects SEM with a more parsimonious correlational model omitting the reciprocal effects (method described in more detail earlier). There was no evidence of directional influences over time because the correlational model described the data as good as the reciprocal model.

Again, there are reasons why the study by Spinath and Spinath (2005b) might not have detected reciprocal effects (see Eccles, 2005). A first reason is that the different constructs were not measured as latent variables. Hence, models were not controlled for measurement errors and this might have masked true effects. A second reason is that the interval between measurement occasions might have been too long. As a third reason, it might be argued that intrinsic motivation and competence beliefs need to be measured domain specifically to find reciprocal influences. The present investigation reacts to all these arguments and measures the constructs on a latent basis, employs shorter measurement intervals, and investigates two domains (math and German) as well as school in general.

The only study using SEM that found evidence for reciprocal relations between an indicator of intrinsic motivation and competence beliefs was reported by Marsh, Trautwein, Lüdtke, Köller, and Baumert (2005). Two large samples of seventh graders gave self-reports on mathematical ability self-concept and interest twice within one school year. These authors found significant reciprocal standardized path weights (ranging from .04 to .10) between ability self-concept and interest. Although this methodologically sophisticated study produced evidence in favor of a reciprocal relationship over time, the effects were rather small and ran in both directions; that is, prior competence beliefs had effects on subsequent interest and vice versa.

One difference that might account for the inconsistent findings of the studies by Marsh et al. (2005) and Spinath and Spinath (2005b) is that the first assessed domain-specific competence beliefs and intrinsic motivation, whereas the latter focused on school in general. As mentioned before, assessing intrinsic values and competence beliefs on a more general level might mask reciprocal effects. In order to investigate whether there are differences between domains as well as between more and less specific measures, the present study compares domain-specific and domain-general intrinsic values and competence beliefs.

Taken together, previous studies suggest a need for stronger evidence supporting claims about the reciprocal effects between measures of intrinsic motivation and competence beliefs over time. Among the aforementioned studies, only three are largely, although not in every detail, in line with the guidelines proposed for the investigation of reciprocal relations in longitudinal studies (Marsh et al., 1999). Moreover, the studies cited above differ in several respects, ranging from different investigated age groups, domains, and indicators of intrinsic motivation to the use of different methodological approaches. Such differences might account for inconsistencies in empirical results.

The Present Investigation

The present study investigated whether intrinsic motivation and competence beliefs show reciprocal influences over time. Specifically, we investigated the assumption that intrinsic motivation to learn declines as a consequence of children's increasingly realistic and therefore less positive ability self-concepts. An answer to this question is given by addressing five individual aspects:

1. Do intrinsic values and competences beliefs decline during the investigated timespan? Such declines need to be investigated both in terms of an overall decline of the means of intrinsic values and competence beliefs in the sample as well as interindividual differences in these developments.
2. How stable are intrinsic values and competence beliefs over time? This is an important question because the more stable the two constructs are, the smaller the chance to find cross-lagged effects over time between them.
3. How strong are the concurrent correlations between the two concepts? The frequently observed medium to strong correlations between intrinsic values and competence beliefs gave rise to the assumption of causal influences between the two constructs.
4. Are prior competence beliefs and subsequent intrinsic values related over time when controlling for prior intrinsic values? And, vice versa, are prior intrinsic values and subsequent competence beliefs related when controlling for prior competence beliefs? Finding such relations over time would be in line with the assumption of causal influences between competence beliefs and intrinsic motivation.
5. Does a theoretical model that includes cross-lagged paths between intrinsic motivation and competence beliefs describe the empirical data better than a more parsimonious model with correlational paths but without cross-paths? This comparison of the two competing models is a second test of the assumption that intrinsic values and competence beliefs might share reciprocal, potentially causal effects over time.

Method

Participants

In 2002 and 2003, 22 third-grade classes from 13 German elementary schools in and around a midsized town were included in the investigation comprising a sample of 670 students. At the time of the first measurement occasion (June 2002), children were on average 8.8 years old ($SD = 0.51$). The investigation lasted 1 year so that children were 1 year older at the last measurement (May 2003). At the first measurement occasion, children were at the end of second grade, and at the last measurement occasion, children approached the end of third grade. The sample was roughly balanced for gender, with 297 (44.3%) of the children being boys. Most of the students were Caucasian (more than 98%) with German citizenship (86%). As typical for an elementary school student population of that cohort and region, children with Turkish citizenship (8%) represented the largest minority group.

Measures

Intrinsic values. Intrinsic values for math, German, and school in general were assessed by means of three items each. Children were asked to indicate on a 5-point scale ranging form *very much* (1) to *not at all* (5) how much they liked each of three different activities or school in general. The items read: "How much do you like mental arithmetics/math problems/doing calculations?" (math); "How much do you like reading/writing (stories, letters)/practicing spelling?" (German); "How much do you like the things you do in school/going to school/How much fun is school to you?" (school in general). For a better intuitive understanding of the scales, we recoded all items so that in the following higher scores denote higher intrinsic values.

A confirmatory factor analysis of the three correlated intrinsic value factors, conducted via SEM, yielded a good model fit at all four measurement occasions (comparative fit index [CFI] = 0.96 to 0.97; root mean square error of approximation [RMSEA] = .06 at all measurement occasions). Standardized path coefficients from the latent intrinsic value factors to the observed variables ranged from .52 to .90 (school in general), .61 to .81 (math), and .45 to .69 (German). Averaged over the four measurement occasions, the reliabilities of the intrinsic value scales were αs = .79, .73, and .53 (school in general, math, German). Because in math and in German, the items represent different activities that constitute each domain, the low internal consistency for German might represent the heterogeneity of this domain rather than a weakness of the scale. For heterogeneous domains, the alpha coefficient is not the appropriate reliability measure and other indicators, such as test–retest reliability, should also be considered. As depicted in

Table 4, test–retest reliabilities of the intrinsic values scale for German are higher than the internal consistencies and are at least satisfactory ($r_{tt} > .63$).

Competence beliefs. Children's competence beliefs for math, German, and school in general were assessed by means of three items each. The items were answered on 5-point scales and read: "How good are you at math/German/school?" with response choice ranging from *very good* (1) to *very bad* (5); "How easy is it for you to learn new things in math/German/school?" from *very easy* (1) to *very hard* (5); and "To which group of pupils do you belong in German/math/school?" from *the best* (1) to *the worst* (5). Again, items were recoded so that in the following higher scores denote higher competence beliefs.

A confirmatory factor analysis of the three correlated competence belief factors yielded a good model fit at all four measurement occasions (CFI = 0.98 to 0.99; RMSEA = .05 to .06). Standardized path coefficients from the latent competence belief factors to the observed variables ranged from .47 to .83 (school in general), .72 to .91 (math), and .67 to .85 (German). Internal consistencies for the three scales assessing competence beliefs, averaged over all four measurement occasions, were αs = .72, .87, and .83 (school in general, math, German).

Procedures

There was a total of four measurement occasions with an interval of 3 months between each test administration. Pupils were tested during a regular class in their classrooms. The testing took about 30 min and was conducted by teachers who did not teach in the tested class. Teachers had been trained to administer the items. Each item was read aloud to harmonize students' working speed.

Statistical Analyses

Missing data. As in all longitudinal studies, sample attrition needs to be taken care of. In the present study, missing data occurred when children missed class the day the testing took place. The main reason for absence was illness. We are not aware of any other reasons for children to miss the testing that might be systematically related to the testing and investigated variables. At each measurement occasion, approximately 80 students did not participate. Table 1 gives information about how many students participated at each measurement occasion. A total of 670 students participated at least at two measurement occasions. Complete data sets for all four measurements were available for 362 students, 270 students participated at three measurement occasions, and 38 participated at two measurement occasions. None of the children missed three measurement occasions. We tried to further explore the nature of the sample depletion by comparing children with missing measurements with the sample of complete data sets. We found no systematic differences in any investigated variable, age, or sex. Furthermore, there were only small amounts of missing data for individual items (less than 1%).

Instead of concentrating on the subsample that completed all measurement occasions, we accounted for missing data by means of full information maximum likelihood (FIML) estimations. We did so for two reasons. First, to maximize statistical power, it is desirable to include as many cases as possible in the analyses. Second, in longitudinal studies, it is difficult to show that data are missing at random and not in any way systematically. Studies indicate that even if data are not missing at random, FIML is still a more effective way of handling missing data than traditional procedures, such as listwise deletion, single- or

Table 1
Means, Standard Deviations, Subsample Without Missing Data (n), and Reliabilities (α) for Intrinsic Values and Competence Beliefs Scales in Three Domains for All Four Measurement Occasions

two-way imputation (Enders, 2001; D. A. Newman, 2003).

Recent research demonstrates that the FIML approach is a potent algorithm for handling missing values (Allison, 2001; Collins, Schafer, & Kam, 2001). By means of FIML, rather than missing values being imputed, missing data are recognized as such, and all observed data values are used to estimate models maximizing the power of the analyses (see Allison, 2001).

Latent growth modeling. To test whether intrinsic values and competence beliefs decreased over time (see Research Question 1), latent growth modeling (LGM) procedures were run using Amos 7.0 (McArdle & Epstein, 1987; Stoolmiller, 1995). We chose LGM for several reasons. First, LGM has been found to have more power in detecting changes over time than repeated measures analysis of variance (Fan & Fan, 2005). Second, when using LGM missing data can be handled by FIML. Third, by applying LGM, both inter- and intraindividual differences in changes over time are considered (McArdle & Epstein, 1987). Six models (competence beliefs and intrinsic values in three domains each) were set up with four measurement occasions as well as a correlated latent intercept and slope factor.

SEM. Data were analyzed by computing longitudinal SEM with Amos 7.0. For each of the three domains (math, German, school in general), we set up two competing models to describe the empirical data: one cross-lagged model (Figure 1a) and one correlational model (Figure 1b). Spanning 1 year, the models employed four measurement occasions. The two latent constructs intrinsic values and competence beliefs were indicated by three items each at each measurement occasion.

By means of SEM, the four remaining research questions were addressed:

1. How stable are intrinsic values and competence beliefs over time? This is indicated by the magnitude of the association each constructs shows with itself from one measurement occasion to the next.
2. How strong are the concurrent correlations between the two concepts? This is indicated by the strength of association between intrinsic values and competence beliefs at each measurement occasion.
3. Are prior competence beliefs and subsequent intrinsic values related over time when controlling for prior intrinsic values? And, vice versa, are prior intrinsic values and subsequent competence beliefs related when controlling for prior competence beliefs? The strength of association between the two constructs over time is indicated by the cross-path from one measurement occasion to another. Besides testing the cross-paths running from one measurement occasion to the next, we also tested for cumulative effects from Time 1 to Time 4, that is, over the timespan of 1 year (this was done by three cross-lagged models spanning cross-lagged paths from Time 1 – Time 4).
4. Does a more complex model including cross-lagged paths (Figure 1a) describe the empirical data better than a more parsimonious model with correlational paths but without cross-paths (Figure 1b)? This comparison of the two competing models is a second test of the assumption

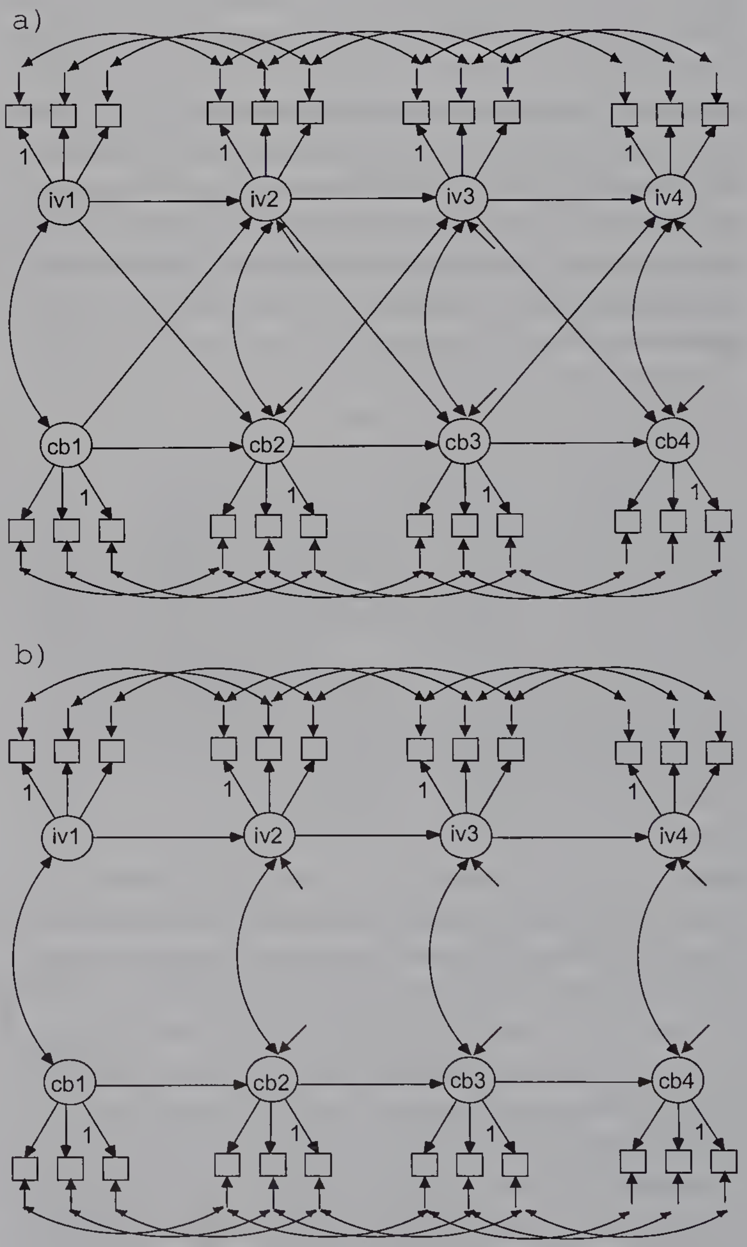

Figure 1. (a) Cross-lagged model: Longitudinal structural equation modeling of intrinsic values (iv) and competence beliefs (cb) including cross-lagged directional paths. (b) Correlational model: Longitudinal structural equation modeling of intrinsic values (iv) and competence beliefs (cb) without cross-lagged directional paths.

> that intrinsic values and competence beliefs might share reciprocal effects over time. According to a basic scientific principle, in the case of two competing models, which describe a phenomenon equally well, the more parsimonious model or theory should be preferred over the more complex one. Although the preference of the more parsimonious model in the case of an equal fit to the data does not rule out the existence of cross-lagged effects, such effects would be rather weak.

Figure 1a depicts the hypothesized cross-lagged effects model (cross-lagged model) employing four measurement occasions. This model allowed for testing further models nested in it. The correlational model (Figure 1b) was modeled with additionally constraining the cross-lagged paths to zero. Thus, the correlational model omits cross-lagged directional paths between the two constructs. The more parsimonious model should be preferred over the more complex model provided that omitting the cross-paths does not deteriorate the model fit (Neale & Cardon, 1992). Differences in fit between nested models were tested by means of likelihood ratio tests. Furthermore, the Tucker – Lewis index was used, a CFI showing the proportional improvement in model fit of one model in comparison to another.

Beside the models employing all four measurement occasions (t1-2-3-4 models), we also tested models for the longest possible time interval, incorporating direct paths from the first to the last measurement occasion (t1-4 models). Here, we also compared t1-4 models with and without cross-lagged effects and named them t1-4 cross-lagged and t1-4 correlational models.

To control for potential memory effects and, thus, positively overestimated stabilities between the different measurement occasions, models were set up with correlated uniqueness between all corresponding measures collected at subsequent measurement occasions. To identify the model, residual variances were constrained.

For the evaluation of overall model fit, three different fit indices were used (see Hu & Bentler, 1999): chi-square value, RMSEA, and CFI. According to Browne and Cudeck (1993), an RMSEA $\leq .05$ indicates a very good model fit and an RMSEA $\leq .09$ is still an indicator for a reasonable error of approximation. According to Hu and Bentler (1995), it is difficult to provide a recommended range for the CFI because in some cases even a CFI < 0.90 can indicate a reasonable model fit. Usually one looks for a CFI ≥ 0.95.

Results

Descriptives

Means, standard deviations, and reliabilities are shown in Table 1. Means of all scales are above the theoretical mean, which signals a potential violation of the normal distribution assumption. In fact, all scales are skewed to the positive pole, as is always the case with these concepts in young children. However, this should not affect the present analyses because maximum likelihood estimations are robust against such violations in the case of large samples, that is, $N > 400$ (see Schermelleh-Engel, Moosbrugger, & Müller, 2003).

Latent Growth Modeling

LGMs were employed to test whether intrinsic values and competence beliefs decreased over time. Results for the six LGMs are depicted in Table 2. The second to fourth columns depict different fit indices for the models (chi-square, RMSEA, and CFI). Model fit for all models was at least satisfactory. The fifth and the sixth columns depict the estimations of the intercept factor and its standard deviations (*M* IC and *SD* IC). The intercept factor represents the average starting point of the construct at t1 and conveys the same information as the means and standard deviations of the first measurement occasion presented in Table 1.

Columns 7 and 8 depict the estimation of the means of the slope factor as well as its standard deviations (*M* Slope and *SD* Slope). The slope factor represents the average change of the constructs over the four measurement occasions. The mean of the slope factor (*M* Slope) was significant for all models with the exception of intrinsic values for German. For these five models, the decline over time was small with scores decreasing by .09 – .15 units. This finding is in line with our assumption that intrinsic values and competence beliefs decline during the early school years.

The standard deviations of the slope factor (*SD* Slope) were significant as well, again with the exception of intrinsic values ascribed to German. This finding indicates interindividual differences in the trajectories.

The ninth column of Table 2 depicts the covariance of the intercept and the slope factor. In accordance with Bast and Reitsma (1997), we do not interpret these covariances because "interpretation of the correlation between status and growth is in most cases not valid" (p. 165) as was also demonstrated by Rovine and Molenaar (1998) by means of simulated data and algebraically.

SEM

Before further interpreting the findings from the SEMs, the general fit of the models to the empirical data needs to be evaluated. Fit indices for the cross-lagged and correlational models with all four measurement occasions (t1-2-3-4) and t1-4 models are depicted in Table 3. CFI and RMSEA fit indices for all models were at least satisfactory, indicating an acceptable to good fit to the data.

Next, we turn to the question of how stable intrinsic values and competence beliefs are over time. Table 4 presents the temporal stabilities for 3-month intervals and for the timespan of 1 year (t1-4). Coefficients are based on maximum likelihood estimations. Considering time intervals of 3 months, temporal stabilities for both constructs were high (ranging from .63 to .87). Over the timespan of 1 year, stabilities were mostly high (ranging from .46 to .70), with the exception of competence beliefs for German (.27). The knowledge that both intrinsic values and competence beliefs are highly stable over time is important because it renders reciprocal effects between the two constructs less probable.

Concurrent correlations between intrinsic values and competence beliefs are of interest because the usually observed strong associations between the two constructs nourish the assumption of mutual influences. Concurrent correlations between intrinsic values and competency beliefs were highest for math (.73 – .83), somewhat lower for German (.60 – .73), and lowest for school in general (.29 – .41), showing that the two constructs are higher correlated within specific domains than for school in general (see Table 5).

Next, we turn to the cross-lagged effects that indicate whether there are reciprocal influences between intrinsic values and competence beliefs. A look at Table 5 reveals that only few significant time lagged cross-paths emerged. Among the cross-paths from competence beliefs to intrinsic values, two of the nine paths reached significance. These two paths were spread over two of the three domains (math and school in general) and two of the three intervals between measurements. Among the cross-paths in the opposite direction, that is from intrinsic values to competence beliefs, none reached significance. When inspecting the longest possible interval between measurements, one of the six cross-paths reached significance, namely, the one from intrinsic values

(t1) to competence beliefs (t4) for German. The magnitude of all significant cross-paths was low. Taken together, these results suggest that there were only minor and unsystematic reciprocal influences between intrinsic values and competence beliefs.

Finally, the correlational models were tested against the cross-lagged models to show whether the more complex cross-lagged models provide a better fit to the data than the mere correlational models. First, we describe the results for the models including all four measurement occasions (t1-2-3-4 models). Concerning school in general and German, the correlational models yielded fit statistics that were as good as those of the cross-lagged models (see Table 6). Omitting the cross-lagged paths did not lead to a deterioration of fit in these two domains. Only in math, the correlational model yielded a deteriorated model fit compared to the cross-lagged model. This effect can be attributed to one single significant path from competence beliefs to intrinsic values from t1 to t2: Constraining this path weight to zero yielded a significant deterioration in fit (discrepancy between chi-squares of cross-lagged and correlational model [CMIN] = 15.93; $df = 1$; $p < .001$), which was not the case when constraining other paths to zero. Therefore, for math, a unidirectional model should be preferred over a correlational, modeling one path from competence beliefs at t1 to intrinsic values at t2. For German and school in general, the cross-lagged paths did not contribute substantially to the model fit. Therefore, the more parsimonious correlational models should be preferred for these two domains.

Turning to the models spanning 1 year (t1-4 models), for school in general, the correlational model yielded no deterioration in fit compared to the cross-lagged model. For German, a deterioration in fit occurred when constraining the path weight from intrinsic values to competence beliefs to zero (CMIN = 7.01; $df = 1$; $p = .01$). In contrast, when constraining the path from competence beliefs to intrinsic values to zero, no significant deterioration in fit occurred (CMIN = .29; $df = 1$; $p = .59$). For math, the model fit deteriorated only when constraining both path weights to zero. Thus, when considering the longest possible timespan of 1 year, for school in general, the correlational model was the most adequate description of the data, whereas for math, a reciprocal cross-lagged model, and for German, a unidirectional model with a cross-path running from intrinsic values to competence beliefs should be preferred.

Taken together, the comparison of model fits of correlational and cross-lagged models suggests that in most cases a correlational model is adequate to describe the empirical data.

Discussion

The main aim of the present study was to shed further light on the question whether the development of intrinsic motivation in the early school years is related to the development of competence beliefs over time. Our study is the first in this field that, simultaneously, incorporates more than two longitudinal

measurement occasions, addresses different specific domains as well as school in general, and models the constructs on a latent basis. Moreover, we investigated children at a phase in their trajectories, which makes normative evaluations very salient and thus would render the finding of reciprocal relations probable.

Declining Competence Beliefs and Intrinsic Motivation

Consistent with previous findings, our results showed that intrinsic motivation and competence beliefs declined throughout the investigated time period (Bouffard et al., 2003; Gottfried et al., 2001; R. S. Newman, 1984; Spinath & Spinath, 2005b; Wigfield et al., 1997). Additionally, we demonstrated significant interindividual differences in the decline; that is, the decrease in competence beliefs and intrinsic motivation is more pronounced for some children and less for others. This is an important finding because some children seem to be more at risk for losing their motivation to learn. Further studies should focus on variables that might explain these interindividual differences in the developmental curves of intrinsic motivation and competence beliefs. Such factors might have the potential to buffer the decline in intrinsic motivation over time.

Temporal Stability of Competence Beliefs and Intrinsic Motivation

Both intrinsic values and competence beliefs were highly stable in terms of interindividual stability over time. The high stability of the two constructs has direct implications for the search of reciprocal effects because the more stable a construct, the lower the possibility of finding other variables that potentially explain variance (see Eccles, 2005). One might argue that in order to find relations between two constructs over time, it is necessary to investigate the phenomenon as early as possible so that maybe the constructs have not yet reached such high interindividual stabilities. Unfortunately, this approach is limited because competence beliefs in the sense operationalized in our study do not emerge before school age (cf. Dweck, 2002) and seem to be highly stable as soon as they are measurable (e.g., Spinath & Spinath, 2005b). Given the high interindividual stabilities, there is a small chance of finding reciprocal influences between competence beliefs and intrinsic values. Whether this means that there actually are no or only weak reciprocal influences needs to be investigated with different methodological approaches. It is a challenging task for future research to find such methodological approaches.

Concurrent Correlations Between Competence Beliefs and Intrinsic Motivation

Concurrent correlations between competence beliefs and intrinsic values were found to be high for specific domains (math and German) and markedly lower for school in general. Such differences in strength of concurrent associations between constructs are important because one could argue that the probability of finding reciprocal effects is higher in domains in which there are stronger concurrent associations. Stronger associations between competence beliefs and intrinsic motivation within specific domains might be explained by considering that when children think about competence and task values in a certain subject, they think of the same material and teacher. However, regarding school in general, one topic may be more strongly reflected when children think about their intrinsic values (e.g., art class) and another when they think of their competence (e.g., geography). This might be a possible explanation for the lower concurrent correlations in the general domain. This result indicates that it is worthwhile to include different domains in one study because the probability of finding reciprocal effects might depend on the degree of association between the constructs.

The reason why intrinsic motivation and competence beliefs are found to be so highly correlated, although they seem not to be linked over time, might lie in the fact that certain experiences, like receiving unfavorable feedback, often affect both competence beliefs and intrinsic values at the same time. Nevertheless, in such situations, decreasing competence beliefs could be independent from decreasing intrinsic values. Even at instances when competence beliefs might realistically decrease after negative feedback, children's intrinsic motivation can stay at the same level or even increase when they are oriented toward learning and when they are convinced that effort will help to overcome initial difficulties. Thus, interventions that focus children on individual progress, learning goals and strengthen their faith in the utility of effort might help to disentangle the developmental curves of competence beliefs and intrinsic values.

Relations Between Competence Beliefs and Intrinsic Motivation Over Time

Concerning the question of potential relations between intrinsic values and competence beliefs over time, our results are in line with previous studies showing that such effects are, if observable at all, of negligible magnitude (Marsh et al., 2005; Nurmi & Aunola, 2005; Skaalvik & Valas, 1999; Spinath & Spinath, 2005b). We conclude this from the observations that, in most cases, mere correlational models provided as good descriptions of the data as more complex cross-lagged models and that cross-paths between intrinsic values and competence beliefs, overall, were very weak. The few significant relations between constructs over time revealed no interpretable pattern: Of 24 cross-paths, only 3 reached significance, which were spread over all three domains as well as different measurements. One path did not run from prior competence beliefs to subsequent intrinsic values but the other way around. All in all, our results indicate that the probability of a relation between ability beliefs and intrinsic values over time is low. After controlling for prior intrinsic values, there are only negligible associations between competence beliefs and subsequent intrinsic values and vice versa.

Before this conclusion is accepted, one needs to exclude methodological reasons, which might have prevented finding reciprocal effects. We took great efforts to design the present study in line with methodological and content-specific recommendations made by experts in the field (Eccles, 2005; Marsh & Yeung, 1997, 1998). Such efforts included longitudinal measurement with four measurement occasions, short intervals between measurements, a midsized sample of elementary school children, latent measurement of constructs, and incorporating different domains. Especially noteworthy is that we investigated children at a period during their school trajectories where normative evaluations become salient because of the onset of grades. Taken together, we believe that those features of the present study rendered the finding of reciprocal relations over time between competence beliefs and intrinsic values especially probable so that neither methodological nor other characteristics of the study account for not finding such associations over time.

Implications for Motivation Theories and Educational Practice

Given the fact that many motivation theories implicitly or explicitly assume that positive competence beliefs are a very important prerequisite for intrinsic motivation and interest (Deci & Ryan, 1985; Harter, 1981a; Wigfield & Eccles, 2000), our results are surprising. We agree that it is a very plausible assumption that individuals should enjoy tasks, which give them reasons to feel competent. But we like to advance the idea that it is not the absolute level of normatively based ability self-perceptions that stimulates feelings of efficacy but other ability-related perceptions and beliefs. Specifically, we argue that perceptions of individual progress and the optimism that competences can be developed should be important to sustain intrinsic motivation in a certain domain.

These kinds of ability-related beliefs have been discussed in different developmentally focused approaches to motivation. For example, Nicholls (1984) distinguishes between two ways in which to conceive ability: Ability can be judged relative to others or with reference to the individual's own past performance. We suggest that children who measure their own competence more often with reference to their past performance instead of comparing it with others' ability should be more strongly intrinsically motivated in the corresponding tasks. A second ability-related concept we want to suggest as a promising candidate for fostering intrinsic motivation are implicit theories about the malleability of ability. The work of Dweck and her colleagues (cf. Dweck, 1999) shows that implicit theories about the malleability of ability are largely independent of the absolute level of self-perceived ability. We expect that children who are convinced that their ability is not a fixed entity but can be increased should be more intrinsically motivated to learn and thus actually increase their competence. To corroborate these theoretical assumptions, future studies should include measures such as perceptions of individual progress and incremental ability theories when investigating influences on intrinsic motivation (see also Spinath & Spinath, 2005b).

With respect to educational practice, the present results allow some speculations about more and less effective methods for fostering high, sustaining intrinsic motivation. Many teachers hold the assumption that declining intrinsic motivation to learn is an inevitable consequence of children's increasingly realistic self-perceptions. Some teachers might therefore try and preserve children's unrealistic ability self-perception by giving either unrealistically positive or vague feedback. Given the present findings, such practices will probably fail to conserve children's intrinsic motivation. The development of realistic ability self-perceptions is an important developmental task, which needs to be supported by realistic feedback. If the decline of intrinsic motivation in school-related learning is not linked to declining competence beliefs, then it should be possible to disentangle the developmental curves of the two constructs. Even in the face of realistically held low ability self-concepts, learners can develop an optimistic, learning-oriented perspective in which they consider low competencies as learning opportunities and learning as an end in itself.

Children's Insecure Representations of the Interparental Relationship and Their School Adjustment: The Mediating Role of Attention Difficulties

Patrick T. Davies and Meredith J. Woitach
University of Rochester

Marcia A. Winter
Syracuse University

E. Mark Cummings
University of Notre Dame

This study examined the role of attention difficulties as a mediator of associations between children's insecure representations of the interparental relationship and their school adjustment in a sample of two hundred and sixteen 6-year-old children. Consistent with hypotheses, findings from structural equation models indicated that observer ratings of children's insecure representations of interparental relationships in a story completion task predicted computerized task assessments and parent reports of children's attention difficulties 1 year later. Children's attention difficulties, in turn, were associated with concurrent levels of school problems and increases in school problems over a 1-year period as indexed by teacher reports. Attention difficulties accounted for an average of 34% of the association between insecure internal representations and school problems.

The significance of interparental discord as a public health concern is highlighted by its association with children's psychological maladjustment. Exposure to high levels of discord increases children's risk for a wide array of psychological problems including internalizing symptoms (e.g., depression, anxiety), externalizing problems (e.g., aggression), social impairments (e.g., poor peer relations), and academic difficulties (e.g., Dunn & Davies, 2001; Erel & Burman, 1995; Grych & Fincham, 2001). The disproportionate vulnerability of children exposed to interparental discord has precipitated calls to understand precisely how and why interparental conflict is associated with children's psychological functioning.

In addressing why interparental strife is a risk factor for children, prevailing theories propose that children's internal representations of the consequences of interparental difficulties are pivotal explanatory mechanisms. According to the emotional security theory (EST; Cummings & Davies, 1996), witnessing destructive interparental conflict sensitizes children to concerns about preserving their security. Threats to security are manifested in children's negative internal representations of the consequences for the welfare of the self and family. Although these representations may be adaptive initially by sharpening children's ability to identify danger cues in high-conflict homes, maladaptive implications for their long-term psychological adjustment are expected (Davies, Winter, & Cicchetti, 2006; Johnston & Roseby, 1997). Similarly, the cognitive-contextual framework hypothesizes that elevated interparental conflict increases children's vulnerability to psychological problems by heightening their appraisals of threat in the family (Grych & Fincham, 1990). Supporting the common prediction of these theories, cross-sectional and longitudinal studies indicate that insecure representations of interparental relations are intermediary mechanisms in associations between interparental conflict and child adjustment (Dadds, Atkinson, Turner, Blums, & Lendich, 1999; Davies & Cummings, 1998; Grych, Fincham, Jouriles, & McDonald, 2000; Grych, Harold,

---

This research was supported by the National Institute of Mental Health (Project R01 MH57318) awarded to Patrick T. Davies and E. Mark Cummings. We are grateful to the children, parents, teachers, and school administrators who participated in this project. Our appreciation is expressed to project staff, including Courtney Forbes, Courtney Henry, Marcie Goeke-Morey, Amy Keller, Michelle Sutton, Alice Schermerhorn, and the graduate and undergraduate students at the University of Rochester and University of Notre Dame. We would also like to thank Melissa Sturge-Apple for her statistical consultation and expertise.

Correspondence concerning this article should be addressed to Patrick T. Davies, Department of Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY 14627. Electronic mail may be sent to patrick.davies@rochester.edu.

& Miles, 2003; Harold, Shelton, Goeke-Morey, & Cummings, 2004).

Although this work documents the importance of negative representations for understanding the development of children exposed to interparental discord, questions of how and why these representations develop into broader patterns of psychological maladjustment remain unexplored. To address this gap, this study examines attention difficulties as possible mediating mechanisms in accounting for links between children's negative representations of interparental relations and their psychological adjustment during the early elementary school years. Guided by a common theoretical focus on the evaluation of threat and safety in internal representation constructs (Davies & Cummings, 1994; Grych & Fincham, 1990), we trace the sequelae of children's insecure representations of interparental relations or, more specifically, their analysis of the threatening repercussions of interparental difficulties for their well-being.

In addressing the first link in our proposed mediational chain, recent conceptual advances in EST provide the groundwork for outlining how children's insecure representations of interparental relations may increase children's risk for experiencing attention difficulties (Davies, Winter, et al., 2006). EST proposes that children's insecure representations of interparental relationships reflect their heightened concerns about preserving their safety and security in the family. Prolonged concerns about security, in turn, set in motion multiple defensive processes that are hypothesized to increase children's risk for adjustment problems by depleting children of biopsychological resources. As a result, insecure children may experience problems with self-regulation across multiple domains, including emotion, cognition, and motivation. Given that directing and sustaining attention require careful coordination of cognitive, affective, regulatory, and motivational processes, concerns about security undermine children's attention. Therefore, insecure representations of interparental relationships may increase children's adjustment problems by disrupting their ability to focus and sustain attention.

Associations between negative family experiences and attention difficulties have been documented. For example, Fearon and Belsky (2004) reported that children with insecure parent–child relationships evidenced elevated attention difficulties under conditions of high cumulative risk (i.e., child, social, and parent risk factors). Likewise, Carlson, Jacobvitz, and Sroufe (1995) found that maternal perceptions of low emotional support from their intimate partners and social network during infancy predicted preschool children's distractibility 2 years later. Thus, even though individual differences in attention difficulties may have constitutional origins that are relatively stable over time, a growing corpus of research supports the role of family environmental factors as precursors to attention difficulties (Groot, de Sonneville, Stins, & Boomsa, 2004; National Institute of Child Health and Human Development [NICHD] Early Child Care Research Network, 2003, 2005).

In the second link in our mediational model, inattention is regarded as a precursor of children's school adjustment problems. For example, attention difficulties may be manifested in impairments in processing relevant contextual cues that act as guides for skillful and appropriate behavioral conduct in social and academic settings. When children are faced with the challenges of adapting to elementary school, attention impairments may contribute to difficulties in establishing harmonious peer relations, exercising self-control, and assuming a cooperative, engaged role in structured classroom contexts (Barkley, Fischer, Smallish, & Fletcher, 2002; Campbell, Pierce, March, Ewing, & Szumowski, 1994). Within clinical and high-risk samples, children with attention difficulties are at greater risk for problems with behavioral conduct, peer relationships, academic achievement, and social engagement (Barkley et al., 2002; Campbell et al., 1994). In community samples, attention impairments during preschool and early school years are identified as concurrent and prospective predictors of lower academic achievement, poorer social competence, and greater externalizing symptoms (NICHD Early Child Care Research Network, 2003). In addition, preschool and elementary school children with difficulties in focusing and shifting attention are at risk for experiencing externalizing symptoms (Eisenberg et al., 2000), poor adaptation to changing demands (Eisenberg, Fabes, Guthrie, & Reiser, 2000), social skill impairments (Eisenberg et al., 1993), and peer problems (Eisenberg et al., 1993).

Our decision to examine mediational pathways among insecure representations of interparental relations, attention difficulties, and child psychological adjustment during the early elementary school years was guided by several considerations. First, significant advances in social perspective taking during this developmental period may elevate the capacity for child worries about family relationships. Thus, internal representations of interparental relationships may assume greater salience in school children's lives as they become increasingly adept at assessing the implications of interparental discord for the welfare of themselves and the family system (Cicchetti, Cummings, Greenberg, & Marvin, 1990). Second, these changes correspond temporally with the emergence and intensification of significant difficulties in sustained attention (Loeber, Green, Lahey, Christ, & Frick, 1992). Accordingly, the early school years provide an informative window for exploring attention difficulties as possible sequelae of negative internal representations. Finally, during this period, children are also faced with the stage-salient task of adjusting to multiple scholastic challenges including regulating behavior, establishing and maintaining peer relationships, and engaging cooperatively in academic activities (Entwisle, 1995; Ladd, Herald, & Andrews, 2006). Because the demands of schooling pose formidable challenges even for children developing along adaptive trajectories, the liabilities associated with insecure representations and attention difficulties for children may be prominent within domains of school adjustment. Thus, this is a critical developmental period for exploring the mediational interplay among representations and attention difficulties in predicting school adjustment.

Breaking new ground methodologically in the study of process variables underlying the impact of representations, we tested the role of attention problems as a mediator of negative representations of interparental relationships using three measurement occasions, each spaced 1 year apart. Employing three measurement occasions generated rigorous tests of our mediator predictions by temporally disaggregating the putative risk factor, mediator, and outcome (Cole & Maxwell, 2003). Therefore, temporally ordered prospective analyses were possible using Wave 1 measures of insecure interparental representations, Wave 2 assessments of attention difficulties, and Wave 3 assessments of school adjustment. Autoregressive analyses, which controlled for prior values of school adjustment and inattention, were conducted to derive more rigorous tests of change in testing mediational pathways (Gollob & Reichardt, 1987). The multimethod, multiinformant measurement battery reduced common method and informant variance and increased confidence for detecting substantively meaningful relationships among the constructs.

Method

Participants

Participants were drawn from a larger project that originally included 235 families recruited through local school districts and community centers in a moderate-sized metropolitan area in the Northeast and a small city in the Midwest. Interested families were included in the project if they met the following eligibility criteria: (a) the primary caregivers had a child in kindergarten, (b) the kindergarten child and two primary caregivers lived together for at least the preceding 3 years, and (c) the primary caregivers and child were fluent in English. Although the criteria did not exclude families with same-sex caregivers, each family in our sample contained a female caregiver, a male caregiver, and a child in kindergarten. Only families who participated in all three waves of data collection were included in this study. The retention rate across all three measurement occasions was 92%. Thus, the final sample for this article consisted of 216 children and their families. The average age of the children at Wave 1 was 6.0 years ($SD = 0.48$); 54% of the sample were girls ($n = 117$) and 46% were boys ($n = 99$).

Median family income for participating families was in the range of $40,000–$54,000, with 11% of the sample reporting household income below $23,000. The average number of years of education completed by mothers and fathers were 14.62 ($SD = 2.25$) and 14.76 ($SD = 2.71$), respectively. A large proportion of the family members reported being White (77%), followed by smaller percentages of Black (16%), Hispanic (3%), Asian American (1%), mixed (2%), and other racial (1%) family members. Families lived together for at least 3 years prior to initial data collection ($M = 5.35$, $SD = 1.06$). Children lived with their biological mother in the majority of cases (95%), with the remainder of the sample living with either an adoptive mother (3%) or a stepmother or female guardian (2%). In addition, children lived with their biological father in the majority of cases (88%), with the remainder of the sample living with either an adoptive father (4%) or a stepfather or male guardian (8%). Minimal differences were found between the present sample ($n = 216$) and the families in the larger sample who did not participate in all waves of the study ($n = 19$). Statistical comparisons of the two groups along 15 demographic variables (e.g., family income, occupational status, race–ethnicity, marital status, age) and the 12 child measures at Waves 1 and 2 (i.e., indices of child insecurity, inattention, and school adjustment) yielded one significant difference: Families in the present sample contained parents with higher education levels than excluded families (Cohen's $d = 0.86$).

Procedures

Data for this study were collected at three measurement occasions, with contiguous measurement occasions spaced 1 year apart. At each wave, families visited the laboratory at one of the two sites. Laboratories at each site were designed to be comparable to each other in size and quality and included (a) an observation room that was designed to resemble a family room and equipped with audiovisual equipment to capture family interactions and (b) interview rooms for completing confidential interview and survey measures. The study was approved by the institutional review board at each research site.

At Wave 1, parents completed abbreviated questionnaires designed to assess attention difficulties. During the Wave 1 visits, children also participated in a revised version of the MacArthur Story Stem Battery (MSSB), a narrative storytelling technique designed to assess child representations of family relationships (Bretherton, Oppenheim, Buchsbaum, Emde, & the MacArthur Narrative Group, 1990). Consistent with the original format of the MSSB, the experimenter conducting the revised version of the MSSB (MSSB–R) introduced a series of story stems describing various stressors and threats to the different family subsystems (Davies, Sturge-Apple, Winter, Cummings, & Farrell, 2006). The MSSB–R is designed to provide a more extensive measurement of child representations of the family system, including three stories each being devoted to assessing threats to the mother–father, mother–child, and father–child relationships. To facilitate child engagement in the task, experimenters used dramatic, animated voices, various toy props, and family action figures matching the child's sex and race. After the experimenter presented each story stem, children completed the story with the assistance of the action figures, props, and various probes and prompts by the experimenter. Given our focus on the security of children's representations of interparental relations, for this study, we only retained the three stories depicting various levels of threat or stress in the interparental relationship: (a) a mild interparental conflict regarding a lost set of keys, (b) an intense interparental conflict regarding a messy kitchen, and (c) a relatively calm interparental disagreement about one of the parents returning home late. Child stories were videotaped for later coding.

At Wave 2, data on attention difficulties were collected with multiple methods and from multiple informants. First, mothers and fathers independently reported on children's attention difficulties through questionnaires. Second, the Continuous Performance Test II (CPT II) was completed by children at Wave 2 to assess their attention difficulties (Conners, 2000). Administration followed standard practices for the task: With an experimenter in the room to oversee the task, children were instructed to watch a series of letters and respond to all the letters except the target letter X by pressing the space bar as quickly as possible. Each letter was displayed for a 250-ms time period. To obtain a more sensitive measure of attention difficulties in the face of the changing demands of the task, time between stimulus (i.e., letter) presentations in the CPT II varied across the task at 1-, 2-, and 4-s intervals. Following a 2-min practice session, children completed six blocks of letter presentations, each lasting approximately 2 min. Each block, in turn, contained three subblocks of 20 trials each.

Finally, children's classroom teachers completed questionnaires at Waves 2 and 3 to assess children's behavioral and social adjustment in school.

Measures

The measurement battery was designed to generate latent constructs of five primary constructs: children's insecure representations of interparental relations at Wave 1, their attention difficulties at Waves 1 and 2, and their school adjustment at Waves 2 and 3. Therefore, each main construct was assessed through multiple indicators.

Insecure internal representations of interparental relations (Wave 1). Coders rated the videotaped records of each of the three interparental narratives from the MSSB–R along four 5-point scales designed to assess child representations of the implications of interparental difficulties for the welfare of the child and family. *Maternal and paternal caregiver incompetence* ratings, which served as two of the indicators of children's insecure representations of interparental relations, were designed to assess the extent to which each caregiver fails to use available resources in ways that protect or improve the integrity of the family. Whereas *very competent* (1) ratings reflect that the child portrays caregivers as sources of support and protection for the child and family in the face of interparental challenges, *very incompetent* (5) ratings reflect that caregivers are depicted as completely ineffective or frightening. As a third indicator, ratings of *relationship quality* were designed to assess children's representations of the long-term emotional impact of the conflict on the interparental relationship. The rating scale ranged from *intense harmony* (1), which reflects expectations that relationships are predominantly harmonious, to *intense discord* (5), reflecting expectations of long-term intense problems between parents. The final indicator, the *emotional insecurity* code, was a global rating designed to assess children's collective representation of the interparental relationship as a source of support or threat. Ratings ranged from *strong security* (1), in which the family relationship is depicted as competently resolving challenges in a manner that facilitates family harmony and the physical and emotional welfare of the child, to *strong insecurity* (5), in which the family relationship is portrayed as a long-term severe threat to the child's security.

Four independent coders, who were trained to reliability, were randomly assigned to code MSSB–R narratives of subsamples of children in the study. To evaluate interrater reliability, all coders were responsible for rating the same subsample (i.e., 20%) of tapes. Intraclass correlation coefficients for each of the four rating scales within each story ranged from .85 to .95 (M = .90).

Attention difficulties (Wave 1). Although our measurement battery did not contain extensive measures of attention difficulties at Wave 1, we used mother and father reports on two questionnaire items as proxy measures of child attention difficulties (i.e., "has a hard time following instructions"; "is good at following instructions"). The items were adapted from the Inhibitory Control Scale of the Child Behavior Questionnaire (CBQ) based on their conceptual correspondence with attention problems (Rothbart, Ahadi, Hersey, & Fisher, 2001). Response alternatives ranged from *extremely untrue of your child* (1) to *extremely true of your child* (7). After recoding the items so that higher scores reflect poorer attention, the four items were averaged together to create a single composite of attention difficulties. The four-item measure evidenced satisfactory internal consistency (α = .73).

Attention difficulties (Wave 2). Attention difficulties at Wave 2 consisted of four indicators. Two measures were derived from the CPT to obtain a balanced, but parsimonious, assessment of children's attention difficulties. First, the *omission error* score was calculated as the percentage of nonresponses to all letters except the target letter X. Thus, higher scores reflect greater difficulties in identifying and responding to the visual stimuli. Second, *variability of standard error*—an assessment of consistency of response times to target stimuli across the test—was defined as the standard deviation of the standard error values of each of the 18 subblocks. Higher scores on this dimension correspond with greater variability in performance across the task and difficulties with sustained attention. The three measures are indexed by T scores that characterize the performance of the children in relation to the normative group according to gender and age. Each of the CPT variables has been shown to have adequate reliability (i.e., split half, test–retest; Conners, 2000). The validity of the CPT assessment is supported by its ability to predict psychological adjustment difficulties (e.g., Conners, 2000; Reeves et al., 2006; Seidel & Joschko, 1990; Zelkowitz, Paris, Guzder, & Feldman, 2001).

The remaining two indicators of attention difficulties were obtained from mother and father reports on the Attentional Focusing scale from the CBQ (Rothbart et al., 2001). The nine items of the scale assess children's temperamental disposition to direct and sustain attention during tasks and activities (e.g., "When picking up toys or other jobs, usually keeps at the task until it's done"; "When drawing or coloring in a book, shows strong concentration"). Response alternatives ranged from *extremely untrue of your child* (1) to *extremely true of your child* (7). Prior research provides evidence for the internal consistency and interrater reliability of the Attentional Focusing scale (Putnam & Rothbart, 2006; Rothbart et al., 2001). In support of its discriminant validity, psychometric analyses revealed no measurement confounding (i.e., item overlap) between the Attentional Focusing scale and psychological symptoms. Likewise, consistent with the assumption that individual differences in temperament may increase the likelihood of child psychological problems, convergent validity of the scale is documented by its power to consistently predict adjustment problems and psychological symptoms (Lemery, Essex, & Smider, 2002). In this sample, alpha coefficients for mother and father reports on the Attentional Focusing scale were .73 and .70, respectively. To be consistent with the CPT assessments, maternal and paternal reports were reverse-scored so that higher values reflect greater attention difficulties.

Children's school adjustment. At Waves 2 and 3, teacher reports on three questionnaire scales were used as indicators of school adjustment. First, to assess the peer component of school adjustment, teachers completed the Prosocial subscale from the Child Behavior Scale (Ladd & Profilet, 1996). The Prosocial subscale contains seven items designed to assess children's supportive behavior toward peers (e.g., "Cooperative with peers"). Teachers responded to each item by selecting one of the three response alternatives (1 = *doesn't apply*, 2 = *applies sometimes*, and 3 = *certainly applies*). Reliability and validity of the measure are supported by several studies (Clark & Ladd, 2000; Ladd & Profilet, 1996). Internal consistency of the scale in our study was satisfactory (αs = .91 and .87 at Waves 2 and 3, respectively).

Second, teacher reports on the Cooperative Participation subscale of the Teacher Rating Scale of School Adjustment were used to assess children's adjustment to classroom demands (Birch & Ladd, 1997). The subscale consists of the sum of seven items designed to assess the extent to which children comply with classroom rules and standards in a responsible, respectful manner (e.g., "Follows teacher's directions"; "Uses classroom materials responsibly"). Response alternatives included *doesn't apply* (0), *sometimes applies* (1), and *certainly applies* (2). Considerable empirical documentation supports the psychometric properties of the Cooperative Participation subscale (e.g., Birch & Ladd, 1997; Ladd & Burgess, 2001). For this sample, alpha coefficients for the subscale for Waves 2 and 3 were .91 and .87, respectively.

Third, teachers completed the Behavioral Competence subscale from the Teacher's Rating Scale of Actual Child Behavior (TRS; Harter & Pike, 1984). The Behavioral Competence scale consists of three items measuring children's behavioral conduct in school. Each item is organized in a sequence of two alternative statements (e.g., "This child usually acts appropriately" or "This child would be better if s/he acted differently"). After selecting which statement best characterized the child, teachers then rated the degree of correspondence between the child and the statement by selecting either "sort of true" or "really true." Responses are quantified along a 4-point scale where 4 corresponds with the endorsement of "really true" to the behaviorally competent statement and 1 signifies the endorsement of "really true" to the behaviorally incompetent statement. The factor structure, internal consistency, and validity of the Behavioral Competence subscale are documented by prior studies (e.g., Harter & Pike, 1984; see also Boivin & Begin, 1989; Webster-Stratton & Lindsay, 1999). For this study, alpha coefficients for the TRS subscale were .91 at Wave 2 and .93 at Wave 3.

Results

Descriptive Analyses

Table 1 depicts the means, standard deviations, and correlations among the main variables in the primary analyses. The means for teacher assessments of child school adjustment were comparable to other large nonclinical and community samples (e.g., Kochenderfer & Ladd, 1996; Ladd & Profilet, 1996; Webster-Stratton & Lindsay, 1999). Likewise, in our sample, mean *T* scores in the low to middle 50s for the three dimensions of attention on the CPT fell within the average (i.e., 45–54) to mildly atypical (i.e., 55–59) range. Correlations among the proposed manifest indicators of the main constructs in Table 1 provided initial support for the operationalization of our measurement model. Correlations among the indicators of each of the constructs were generally moderate to strong in magnitude (see bolded coefficients in Table 1). In support of our proposed pathways, significant interrelationships were evident among Wave 1 dimensions of children's insecure representations, their Wave 2 attention difficulties, and teacher reports of their school adjustment at Waves 2 and 3.

Primary Analyses

Given the significant correlations among observed measures of insecure internal representations of interparental relations, attention difficulties, and school adjustment, we proceeded to test the role of attention difficulties as an explanatory mechanism using structural equation modeling (SEM). SEM analyses were conducted using Amos 7.0 (Arbuckle, 2006), a computer software package that uses the full information maximum likelihood approach to handle missing data. Manifest indicators corresponding to teacher reports on the same subscales were permitted to correlate across measurement occasions for all models specified. To obtain a multimethod, multiinformant index of attention difficulties, the three computer assessments and two parent report measures of attention problems were specified as indicators of a single latent construct. In support of fit of the measurement model, factor loadings for all manifest indicators of the latent constructs were significant in the expected direction ($p < .001$). Standardized loadings of the manifest indicators ranged from .43 to .95 ($M = .77$).

Because mediational tests often require that a significant association exists between the predictor and the outcome (Baron & Kenny, 1986; MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002), we first conducted an SEM, which constrained paths between attention difficulties (i.e., mediator) and school problems (i.e., outcome) at Waves 2 and 3 to 0. In this same model, we estimated the direct, predictive paths between latent constructs of Wave 1 insecure representations and (a) Waves 1 and 2 attention difficulties and (b) Waves 2 and 3 school adjustment problems. To provide conservative tests of prospective associations between interparental insecurity and child functioning, structural paths were also specified between interparental insecurity and school adjustment at Wave 3 after controlling for Wave 2 school adjustment through the specification of autoregressive paths. In support of the precondition for testing mediation, insecure representations of interparental relations predicted lower school functioning at Wave 2, $\beta = -.21$, $p < .01$, and Wave 3, $\beta = -.11$, $p < .05$.

Therefore, we subsequently tested a mediational model in which paths between attention difficulties and school adjustment were freely estimated. The resulting model, which is depicted in Figure 1, provided a good representation of the data, $\chi^2(80, N = 216) = 140.28$, $p < .001$, root mean square error of approximation = 0.06, and χ^2/df ratio = 1.75, comparative fit index = 0.97, and Tucker–Lewis index = 0.95. Inclusion of the structural paths between attention difficulties and school adjustment resulted in notable reductions in the magnitude of the path coefficients between insecure internal representations and school adjustment at Wave 2 (β reduced by 81% from −.21, $p < .01$, to −.04, *ns*) and Wave 3 (β reduced by 64% from −.11, $p < .05$, to −.04, *ns*). Consistent with hypotheses, analysis of the structural paths depicted in Figure 1 indicated that insecure representations at Wave 1 predicted attention difficulties at Wave 2, β = .24, $p < .01$, even after specifying the path between the Wave 1 proxy measure of attention difficulties and Wave 2 attention difficulties, β = .52, $p < .001$. Children's attention difficulties, in turn, were associated with poorer school adjustment at Wave 2, β = −.45, $p < .001$. In addition, even after estimating the autoregressive path between Waves 2 and 3 school adjustment (β = .70, $p < .001$), attention difficulty was a significant predictor of decreases in school adjustment at Wave 3, β = −.25, $p < .01$. In further support of the mediational role of attention difficulties, follow-up tests using MacKinnon et al.'s (2002) procedures for indirect effects indicated that the indirect pathways involving interparental insecurity and attention difficulties were significant in the prediction of child school adjustment at Wave 2, $z' = 2.43$, $p < .05$, and Wave 3, $z' = 2.15$, $p < .05$.

whether inclusion of child gender or research site altered the associations among insecure internal representations, attention difficulties, and school adjustment as covariates or moderators. First, to examine the comparability of the findings with child gender and research site as covariates in the model, we included paths among child gender and research site and each of the latent constructs depicted in the model in Figure 1. Supporting the stability of the mediational findings, the results did not change with the addition of child gender and research site as predictors in the model.

Next, to test the moderating role of child gender and research site, we conducted successive multigroup models by splitting the data by child gender (i.e., boys vs. girls) and research site (i.e., NY vs. IN) for each mediational model. Analyses of whether different processes were operating in models across child gender involved comparing a model in which structural coefficients for the autoregressive and indirect paths were constrained to equivalence across boys and girls with a model in which all parameters were allowed to vary freely across gender. Likewise, corresponding comparisons of constrained and unconstrained models across research site were also conducted. To accommodate the smaller sample sizes resulting from the splitting of the data, it was necessary to conduct the multigroup path analyses using manifest variables for the primary constructs in the model (i.e., internal representations, attention difficulties, school adjustment at each time point). Manifest variables of each primary construct were calculated by standardizing their respective indicators and summing them to form a composite. Comparisons of the constrained and free-to-vary models revealed no difference in fit for either the child gender or the research site analyses, thereby indicating that child gender and research site did not moderate any of the proposed pathways. Thus, the mediational pathways in Figure 1 were statistically indistinguishable across child gender and research site.

Discussion

Although insecure representations of the interparental relationship have been shown to pose a risk for children's psychological adjustment (Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings, 2006), the processes accounting for the vulnerability experienced by children are little explored. Therefore, as a first step in testing a process-oriented model of the implications of emotional security, the objective was to examine children's attention difficulties as potential mediating mechanisms in the link between their insecure representations of interparental relations and psychological adjustment. According to EST, attention problems may develop from elevated concerns about security in the interparental relationship and, in turn, undermine children's functioning in the face of challenges arising in other settings (Davies, Winter, et al., 2006). Supporting this hypothesis, children's insecure representations of interparental relationships at Wave 1 predicted a multimethod, multiinformant assessment of children's attention difficulties 1 year later at Wave 2, even after controlling for Wave 1 assessment of attention difficulties. Attention difficulties, in turn, predicted concurrent school problems and increases in school problems over a 1-year period.

Interpreted within EST, multiple interlocking processes may account for why attention is a mediator of insecure internal representations. If internal representations serve as lenses for simplifying, interpreting, and responding to subsequent challenging contexts, then children who have negative interpretations of interparental relations may be primed to scan and interpret subsequent challenging settings for similar threats (Davies, Winter, et al., 2006; Johnston & Roseby, 1997). In accord with this premise, developmental neuroscience models stress that children who repeatedly experience family discord are disproportionately proficient at processing threatening interpersonal stimuli (e.g., Pollack & Tolley-Schell, 2004). However, this proficiency may occur at the expense of adeptly focusing and sustaining attention in nonthreatening settings (Derryberry & Tucker, 2006). Attention models further suggest that neurological restrictions limit capacities for successfully engaging in multiple, concurrent self-regulatory acts. Thus, representational tendencies to process negative stimuli may conflict with other demands on the attention network (Botvinick, Braver, Barch, Carter, & Cohen, 2001; Rothbart & Posner, 2006; Schimmack, 2005). The resulting cognitive interference may be manifested in disruptions in focusing and sustaining attention on relevant tasks. These difficulties, in turn, may be further expressed through problems in effectively encoding and processing interpersonal signals and communications essential for successfully adapting to social and academic challenges in school (Barkley et al., 2002).

The regulatory depletion model provides a complementary account of how children's insecure representations of interparental relations may give rise to attention difficulties. A primary assumption is that the regulation of responding in one domain of functioning (e.g., social cognitive) causes impairments in other response domains (e.g., cognitive problem-solving abilities) by depleting a shared reservoir of resources (Glass, Singer, & Friedman, 1969; Muraven, Tice, & Baumeister, 1998). By extension, difficulties preserving security may deplete a common pool of self-regulatory resources, thereby creating deficits in other domains of functioning. For example, the tendency for children with insecure representations to experience affective and behavioral dysregulation may create difficulties in persevering on challenging attention tasks. The depletion of resources accompanying insecurity may also engender impairments in inhibitory control, characterized by the tendency to forestall a dominant reaction in favor of a subdominant response. Within the context of attention processing, this may result in difficulties remaining engaged in academic tasks and complying with rules in the face of distractions and growing boredom (Barkley, 1997). Other pathways of resource depletion may also be evident. For example, research has shown that sleep disturbance is an intermediary mechanism linking insecurity in the interparental relationship and children's academic, cognitive, and emotional problems (El-Sheikh, Buckhalt, Cummings, & Keller, 2007; El-Sheikh, Buckhalt, Keller, Cummings, & Acebo, 2007). Thus, one possibility is that insecurity in the interparental relationship may engender attention difficulties in children by disrupting their sleep patterns.

In placing the results in broader perspective, as expected, attention did not fully mediate the link between insecure internal representations of interparental relations and school problems. Thus, consistent with recent formulations of EST (Davies, Winter, et al., 2006), other neurobiological, emotional, and cognitive processes may also act as operative mechanisms in producing the developmental consequences of emotional insecurity. For example, emotion dysregulation, poor inhibitory control, working memory impairments, and perceptual sensitivity to negative stimuli are not only associated with attention difficulties (e.g., Barkley, 1997). These same processes are also conceptualized in EST as mechanisms accounting for why children's concerns about security increase their risk for psychological problems (Davies & Sturge-Apple, 2007). Therefore, emotion dysregulation and executive functioning variables may also help to account for the link between insecure representations and children's adjustment difficulties. In addition, biopsychological models will likely serve as valuable sources of hypotheses about the neurobiological mechanisms (e.g., hypothalamic–pituitary–adrenal axis reactivity to threat, serotonergic system dysregulation) that may underlie the mediational role of attention difficulties (e.g., Van Goozen, Fairchild, Snoek, & Harold, 2007). Therefore, examining the role of attention impairments within a broader model of neuropsychological, biological, and self-regulatory problems is an important research direction.

Several limitations of our study are relevant in interpreting the results. First, although our longitudinal analysis of change is an advance over the predominant use of cross-sectional research on internal representations (for some exceptions, see Grych et al., 2003; Harold et al., 2004), the present results do not fully delineate directionality in relationships between children's insecure representations, attention difficulties, and their school adjustment. For example, even though the moderate to strong magnitude of the path between Waves 1 and 2 attention difficulties lends support for the validity of the Wave 1 inattention variable, the psychometric properties of the abbreviated Wave 1 measure may be weaker than the comparable Wave 2 assessment. As a result, the path between Wave 1 internal representations and Wave 2 attention difficulties may be inflated by our use of a proxy measure of inattention in the autoregressive path. However, with regard to specifying directionality, our primary aim was testing whether Wave 2 attention difficulties predicted subsequent change in school problems. In building our analytic model, we followed Cole and Maxwell's (2003) guidelines for authoritatively testing prospective mediational pathways. Therefore, for reasons of parsimony in already complex model tests and consistent with these guidelines for testing mediational pathways, some pathways (i.e., school outcomes at Wave 1) were not regarded as central components for the analyses.

Second, the autoregressive components of the analyses do not rule out the possible operation of other processes or extraneous variables in accounting for the mediational pathways. For example, it may be possible that the mediational effects of attention difficulties are simply rough markers for the more proximal, mediational role of coexisting neuropsychological and self-regulatory impairments (Barkley et al., 2002). Given the empirical documentation of bidirectional relations between children's adjustment problems and parenting difficulties (e.g., Lytton, 1990; Snyder, Cramer, Afrank, & Patterson, 2005), more complex reciprocal chains of processes may also be operating. For example, it is possible that school and attention difficulties may increase children's insecure representations by directly straining interparental relationships. Including broader assessments of children's responses to interparental conflict and their psychological adjustment in future research would also permit more comprehensive tests of the generalizability of the mediational pathways identified in this study. Thus, as with any study, the present findings should be considered within the larger context of developmental processes.

Third, although the sociodemographic characteristics of our sample were representative of the larger population of families within the Northeastern and Midwestern regions of the United States, our community sample consisted of predominantly White families. Therefore, the relationships documented in this study may not necessarily generalize to families with other racial or ethnic backgrounds or families who are facing considerable adversity. Suggestions regarding how our findings could differ across social and demographic conditions are highly speculative at this early stage of research. However, consideration of these factors raises interesting questions. For example, it is possible that African American and Hispanic children may be less susceptible to the deleterious effects of insecurity because extended family networks increase children's access to sources of support (McLoyd, Harper, & Cooper, 2001). In addition, exposure to multiple forms of adversity (e.g., poverty, violence, neuropsychological impairments) that are commonly found in higher risk samples may also be such powerful predictors of children's adjustment problems that they override the effects of insecurity (Davies, Winter, et al., 2006). Therefore, understanding how various contextual and demographic variables may alter the pathways of insecurity is an important research direction.

Despite these limitations, the longitudinal findings of this multimethod study support the hypothesis that difficulty in focusing and sustaining attention is a key mechanism in explaining why children's insecure representations of interparental relations increase their risk for experiencing problems in school. From a scientific perspective, this study represents the first attempt to identify possible mechanisms mediating children's emotional insecurity. As such, it may provide a blueprint for formulating and testing other possible mechanisms that mediate insecurity. In addition, although care should be exercised in applying our results to clinical practice, the findings may serve as guideposts in the development of clinical goals and tools for prevention and intervention programs targeting children from discordant homes. EST specifically proposes that insecure representations of family relationships reflect dispositions to identify and process threatening events in the family. In high-conflict homes, this insecure prototype of scanning the family context for danger has high adaptive value for children because it permits them quickly identify and cope with conflict before it becomes a bigger threat. Thus, implementing prevention and intervention programs designed to alter their insecure representations may be ineffective or even harmful for many children. Therefore, focusing on interrupting the pathogenic processes set in motion by children's concerns about security may be a feasible alternative to treatment programs designed to alter children's patterns of processing or responding to interparental conflict (Davies et al., 2006). The results in the present study specifically support the notion that children's attention difficulties is a key pathogenic process that accounts for the link between their insecure representations of the interparental relationship and their scholastic adjustment problems. Interpreted in this context, our mediational findings suggest that programs designed to optimize attention processes in social and academic settings may provide one method for protecting children from the negative sequelae associated with insecure representations.

Developmental Trajectories of Sex-Typed Behavior in Boys and Girls: A Longitudinal General Population Study of Children Aged 2.5–8 Years

Susan Golombok, John Rust,
Karyofyllis Zervoulis, and Tim Croudace
University of Cambridge

Melissa Hines
University of Cambridge

The stability of sex-typed behavior from the preschool to the middle school years was examined. The Preschool Activities Inventory, a measure of within-sex variation in sex-typed behavior, was completed by the primary caregiver when the child was 2.5, 3.5, and 5 years, and a modified version, the Child Activities Inventory, was completed by the child at age 8. The investigation involved a general population sample of 2,726 boys and 2,775 girls. Sex-typed behavior increased through the preschool years, and those children who were the most sex typed at age 2.5 were still the most sex typed at age 5, with those children who showed the highest levels of sex-typed behavior during the preschool years continuing to do so at age 8.

From an early age, boys and girls differ in their behavior (for a review, see Ruble, Martin, & Berenbaum, 2006). This does not mean that all boys engage in typically male behaviors, or that all girls engage in typically female behaviors, all the time. There is a great deal of overlap between the sexes with some girls being more "boyish" than the average boy and some boys behaving in ways that are more typical of a "girlish" girl. One of the most striking differences between boys and girls is their preference for different types of toys. This can be detected in 1-year-olds (Snow, Jacklin, & Maccoby, 1983), and by 3 years of age, girls are much more likely than boys to play with dolls, dolls' houses, tea sets, and other domestic toys, whereas boys are more often found with toy guns, swords, cars, trains, and trucks (Dunn & Hughes, 2001; O'Brien & Huston, 1985; Servin, Bohlin, & Berlin, 1999; Sutton-Smith & Rosenberg, 1971). This sex difference in toy preferences continues to characterize the preschool and early school years. For example, in a study of 3- to 5-year-olds, a greater preference was demonstrated among boys for a car, an airplane, and a tool set, and among girls for a tea set, a doll, and a hair care set (Martin, Wood, & Little, 1990). Children in this study were also more likely to report that they preferred unfamiliar neutral items such as a pizza cutter and a hole puncher if presented to them as something that children of their sex really like.

In addition, sex differences in playmate preference become apparent in the preschool years. From as early as 3 years of age, girls prefer other girls as playmates and boys prefer to play with boys (Maccoby & Jacklin, 1987). This phenomenon, known as gender segregation, is not specific to particular nationalities or cultures. Children's preference for same-sex playmates is a universal aspect of growing up (Whiting & Edwards, 1988). Gender segregation is most likely to occur when children are not with adults, especially when they are with others of a similar age. In a study of children in a day-care setting, the tendency for girls to play together was observed at age 2 (LaFreniere, Strayor, & Gauthier, 1984). For boys, the preference for male playmates began slightly later but was clearly established at 3 years of age. Howes (1988) reported

---

We are extremely grateful to all the families who took part in this study, the midwives for their help in recruiting them, and the whole Avon Longitudinal Study of Parents and Children (ALSPAC) team, which includes interviewers, computer and laboratory technicians, clerical workers, research scientists, volunteers, managers, receptionists, and nurses. The UK Medical Research Council, the Wellcome Trust, and the University of Bristol provide core support for ALSPAC. This research was specifically funded by the Wellcome Trust.

similar findings. Like LaFreniere et al., she observed children in day care and showed that 3-year-olds were more likely to form new friendships with children of the same sex. Gender segregation is also an important feature of the early school years. Maccoby and Jacklin (1987) examined the playmate preferences of 100 children at 4.5 years of age and again at 6.5 years. When first observed, the children were spending nearly 3 times as much time playing with same-sex peers than other-sex peers. By the second observation, only 2 years later, the amount of time spent playing with same-sex peers was more than 10 times greater than that spent with peers of the other sex. A similar increase in the preference for same-sex peers was demonstrated in a comparison between children in kindergarten and children in the early school years by Serbin, Powlishta, and Gulko (1993). The process of gender segregation involves not only the preference for same-sex playmates but also the avoidance of playmates of the other sex.

Differences in the play styles of boys and girls can also be seen from 3 years of age (Maccoby, 1998; Maccoby & Jacklin, 1987; Pitcher & Shultz, 1983). Boys tend to play in a more active, rough-and-tumble and sometimes physically aggressive, fashion than girls, who tend to talk more to each other and be more nurturant than boys. When girls are aggressive, this is more likely to take the form of behaviors intended to damage relationships such as exclusion from a circle of friends (Crick, Casas, & Mosher, 1997; McNeilly-Choque, Hart, Robinson, Nelson, & Olsen, 1996). Boys also like to play outdoors in large groups, whereas girls are more often to be found in twos and threes indoors. Differences in the way in which boys and girls resolve conflict are also apparent from age 3. Whereas girls incline toward reaching a compromise, it is more common for boys to use physical force (Sheldon, 1990). In addition, pretend play differentiates the sexes, with boys acting out heroic roles involving fighting and adventure and girls preferring to be family characters or dressing up in feminine clothes. As children move from preschool to the early school years, the play styles of boys and girls continue to diverge. Achieving dominance appears to be of particular importance to boys. In order to have status, boys need to be seen as "tough" (Maccoby, 1998). The way in which boys and girls communicate is also different. Girls talk to each other to form and strengthen relationships. Boys use language to give information, assert themselves, and command attention (Lever, 1976; Maccoby & Jacklin, 1987). Boys of this age like to play in large groups of other boys, whereas girls prefer the company of one or two female friends (Fabes, Martin, & Hanish, 2003; Maccoby, 2002). The nature of these relationships also differs between the sexes. Whereas girls' friendships are characterized by emotional and physical closeness, the friendships of boys are founded on shared activities and interests (Maccoby, 1998).

Although there is much evidence from comparisons between the sexes to show that group differences in behavior persist from early to middle childhood, little is known about the extent to which within-sex differences remain stable over time, that is, whether girls or boys who show very feminine, or very masculine, behavior at an early age continue to do so as they progress from the preschool to the middle school years (Ruble et al., 2006). One exception is Martin and Fabes's (2001) observational study of preschool children that demonstrated stability in sex-segregated play for boys and girls over a period of 6 months. A difficulty in addressing this question has been the lack of an assessment instrument designed to measure within-sex variation in gender role behavior that is suitable for use with large samples. A number of questionnaires have been developed to examine gender development in young children (see Beere, 1990, for a review). However, these have focused on between-sex, rather than within-sex, differences. An exception is the Preschool Activities Inventory (PSAI), a psychometrically constructed questionnaire specifically designed to differentiate "masculine" from "feminine" boys, and "masculine" from "feminine" girls, within a normal population sample, that is, to differentiate within, as well as between, the sexes. During the construction of the PSAI, items that, while discriminating between the sexes, failed to differentiate between masculine and feminine boys, or between masculine and feminine girls, were excluded. For more details of the construction of the PSAI, see Golombok and Rust (1993a, 1993b, 2007). Thus, the PSAI is ideally suited to the investigation of stability and change in the gender development of boys and girls. The present study became possible through collaboration with the Avon Longitudinal Study of Parents and Children, (ALSPAC), the first general population data set to include an assessment of childhood gender role behavior. The PSAI was administered when the children were aged 2.5, 3.5, and 5 years old, and an age-appropriate modified version, the Children's Activities Inventory (CAI), was administered at age 8. The aims of the present investigation were to examine (a) the stability of gender role behavior from the preschool to the middle school years, that is, to establish whether "masculine" boys and "feminine" girls, and "feminine" boys and "masculine" girls, continue to show sex-typed and cross-sex-typed behavior, respectively, as they grow up; (b) change in gender role behavior from the preschool to the middle school years, that is, to establish whether boys and/or girls become more or less sex typed as they grow up; and (c) whether "masculine" boys and "feminine" girls show more or less change in sex-typed behavior than "feminine" boys and "masculine" girls, that is, to establish whether sex-typed children show greater change in sex-typed behavior as they grow up than their cross-sex-typed counterparts.

A range of theories have been put forward to explain the processes involved in children's acquisition of sex-typed behavior, the most influential of which have arisen from biological, that is, early hormonal (Hines, 2004), social learning (Bandura, 1977; Mischel, 1966, 1970), and cognitive developmental (Kohlberg, 1966; Martin, 1993) perspectives. It is now generally agreed that sex differences in behavior result from an interplay among biological, psychological, and social mechanisms from early fetal development onward (Bussey & Bandura, 1999; Golombok & Fivush, 1994; Ruble et al., 2006). These perspectives would each predict stability in sex-typed behavior from ages 2.5 to 8 years old as biological influences would be expected to be maintained postnatally, the processes of differential reinforcement and modeling that characterize the classic social learning approach are apparent and are probably relatively stable throughout this age range, and the cognitive processes of gender concept formation and gender schematization occur during the preschool and middle school years. In addition, cognitive developmental explanations of gender development would predict an increase in sex-typed behavior as children grow older as it is argued that children must progress from the stage of basic gender identity through gender stability to reach the stage of gender constancy at around age 5 years and that sex-typed behavior becomes more pronounced as genetic schemas are elaborated. It is important to differentiate between sex-typed behavior and gender stereotyping, the latter of which becomes more flexible at ages 7–8 years (Ruble et al., 2006). To the extent that the processes described by the different theoretical perspectives work together in the development of sex-typed behavior, with inborn hormonal mechanisms forming the basis on which postnatal social and cognitive processes build, it may be expected that sex-typed behavior would not simply remain stable but would increase between the preschool and the middle school years. Social learning and cognitive perspectives might also predict that children who are highly sex typed as toddlers would become even more sex typed over time as these children may receive greater exposure to, and may be more likely to seek out, social and psychological influences that promote sex-typical development, such as interaction with same-sex peers, as they grow up.

Method

Participants

The sample was obtained from the ALSPAC, a geographic population study of almost 14,000 mothers and their children beginning in pregnancy (Golding, Pembrey, Jones, & the ALSPAC Study Team, 2001). The study enrolled all pregnant women who were resident within Avon, a clearly defined area of southwest England, who had an expected delivery date between April 1, 1991, and December 21, 1992. It was estimated that approximately 90% of the eligible population took part. The study area has a population of 1 million comprising the city of Bristol, with a population of 0.5 million, moderate-sized towns, and rural areas. The demographic characteristics of families in the study are closely comparable to those of families in the United Kingdom as a whole with respect to the type of area in which they live, the educational level of the parents, housing, and mobility (Baker, Morris, & Taylor, 1997). The children in the study are similar to children in the rest of the country with respect to the prevalence of preterm delivery, low birth weight, physical and mental disability, physical illness, and psychological disorder.

As part of the ALSPAC study, all mothers or primary caregivers were asked to complete the PSAI (Golombok & Rust, 1993a, 1993b, 2007) when the ALSPAC child was aged 2.5, 3.5, and 5 years old. The children themselves were administered the CAI (Golombok & Rust, 2007) at 8 years old. The present investigation involved 5,501 children (2,726 boys and 2,775 girls) for whom data were obtained at all four time points.

Measures

The PSAI is a questionnaire measure for which a parent or the child's primary caregiver indicates their child's involvement in a variety of sex-typed behaviors. The PSAI comprises 24 items, 12 masculine and 12 feminine, and is divided into three sections: *toys* (7 items), *activities* (11 items), and *characteristics* (6 items). Each section has its own stem. For toys, this is "Please answer the questions according to how often the child played with the following toys during the past month" and an example item is "Jewelry."

For activities, the stem is "Please answer the questions according to how often the child engaged in the following activities during the past month" and an example item is "Fighting." For characteristics, the stem "Please answer the questions according to how often the child showed the following characteristics" is used, and an example item is "Interest in snakes, spiders or insects." Each item is scored on a 5-point scale ranging from *never* through *hardly ever*, *sometimes*, and *often* to *very often*. The feminine items are reversed so that higher total scores represent more masculine-typical behavior and lower total scores represent more feminine-typical behavior. Thus, the higher the total score, the more masculine the behavior for both boys and girls. A benefit of reversing half of the scores in this way is that the effects of acquiescence, that is, the tendency of respondents to agree or disagree with an item regardless of its content, and of differences in level of overall activity, are balanced. The measure has been standardized on more than 2,000 children in the United Kingdom, the Netherlands, and the United States (Golombok & Rust, 1993a). Mean standardized scores on the inventory did not differ for children from these three countries and for the entire group were 61.66 (*SD* = 9.40) for boys and 38.72 (*SD* = 9.66) for girls. The standardization target was a mean of 40 (*SD* = 10) for girls and a mean of 60 (*SD* = 10) for boys. Split-half reliability was .66 for boys and .80 for girls, and test–retest reliability over a 1-year period was .62 for boys and .66 for girls. The inventory has been validated by comparing parental ratings to teacher ratings for children attending five different day-care centers. For boys, the correlation between parent and teacher ratings was .37, and for girls the correlation was .48, showing the inventory to be a valid measure of gender role.

The CAI is an adaptation of the PSAI for children aged 7–8 years old. Unlike the PSAI, the CAI is completed by the child rather than the parent or primary caregiver. Instead of giving the measure as a written questionnaire, the CAI is administered as a task using Harter's format as described below. The PSAI items were transformed to the Harter format in a pilot study, some additional age-appropriate items were included, and the instrument was shortened to 16 items on the basis of item analysis. The child is presented with two postboxes, one blue and one red, with two slots in each. The researcher then reads out a statement written on an envelope in blue ink (e.g., "Some children play with jewelry") while patting the blue postbox, followed by a statement written on a separate envelope in red ink (e.g., "But other children don't play with jewelry") while patting the red postbox. The child is then asked which group of children she/he feels most similar to. If she/he replies that she/he feels similar to the children who play with jewelry, she/he is asked to put the envelope with the blue writing in the blue postbox. If she/he replies that she/he feels similar to the children who do not play with jewelry, she/he is asked to put the envelope with the red writing in the red postbox. The child also has to choose which of the two slots to post the letter into by deciding if the statement is "really true" or "sort of true" of him or her. The researcher points to each slot in the postbox, labeled accordingly, while explaining this to the child. The child then posts the envelope into the slot that represents his or her response. Like the PSAI, the CAI was standardized to give a mean score of 40 (*SD* = 10) for girls and a mean score of 60 (*SD* = 10) for boys, thus allowing the means for the PSAI and the CAI to be compared. Split-half reliability for the CAI is .64 for both boys and girls.

Results

The means and standard deviations of the PSAI at ages 2.5, 3.5, and 5 years, and for the CAI at age 8 years, are presented in Table 1, showing that the instrument differentiates between boys and girls. As the distribution of both PSAI and CAI scores for the sexes combined is bimodal, the analyses were conducted for boys and girls separately unless stated otherwise. The split-half reliabilities also appear in Table 1.

Stability (test–retest reliability) was examined between all three PSAI measures (ages 2.5, 3.5, and 5 years). Stability coefficients for the PSAI between 2.5 years and 3.5 years, 2.5 years and 5 years, and 3.5 years and 5 years were .65, .52, and .68, respectively, for boys, and .63, .53, and .70, respectively, for girls, demonstrating high stability over time. All these correlations were significant at the 0.001 level.

As the measures were repeated over more than two time points, a multilevel modeling approach (MLM) was used to examine the nature of change over time. Multilevel models are models for data that are organized hierarchically and is a generic term for all models for hierarchical or nested data. In the present case, it refers to the nested structure of repeated measurements on individuals over time. Multilevel models yield the same results whether from a hierarchical linear or latent growth perspective. A series of MLM analyses were carried out using the SPSS mixed models program. MLM using this procedure enables the testing of two questions (a) On average, is there a change in sex-typed behavior over time? (b) Are there differences between children in change in sex-typed behavior over time (i.e., do some children

Table 1

Descriptive Statistics of Preschool Activities Inventory Scores and of Children's Activity Inventory Scores (Mean, SD, and Split-Half Reliability)

	Preschool Activities Inventory (30 months)		Preschool Activities Inventory (42 months)		Preschool Activities Inventory (57 months)		Children's Activities Inventory (8 years)	
	M (*SD*)	Split half	*M* (*SD*)	Split half	*M* (*SD*)	Split half	*M* (*SD*)	Split half
Boys (2,726)	60.23 (8.33)	.73	62.07 (8.78)	.77	64.18 (8.77)	.80	59.72 (11.48)	.64
Girls (2,775)	40.90 (8.31)	.73	37.04 (9.81)	.80	35.11 (9.41)	.84	39.95 (12.35)	.64

change more than other children)? A further advantage of this approach is that it generates maximum likelihood estimates of trajectories of sex-typed behavior over time for each child, and these can be correlated with other variables to examine the relationship between the trajectories and the extraneous variables.

Using the full data set of boys and girls combined, a trajectory analysis model was fitted to establish (a) the extent of the sex difference in PSAI scores and (b) the extent of the sex difference in the overall change in PSAI scores over time, that is, the difference between boys and girls in change over time. The model fitted was:

$$\mathrm{PSAI}_{ti} = \gamma_{00} + \gamma_{01}\mathrm{Sex}_i + \gamma_{10}\mathrm{Time}_{ti} + \mathrm{U}_{1i}\mathrm{Time}_{ti} \times \mathrm{Sex}_i + \mathrm{U}_{1i}\mathrm{Time}_{ti} + \mathrm{U}_{0i} + e_{ti}$$

Where PSAI_{ti} is the PSAI score of Child 1 at time t, γ_{00} = is the grand intercept, $\gamma_{01}\mathrm{Sex}_i$ represents between-sex differences, $\gamma_{10}\mathrm{Time}_{ti}$ is the grand slope, $\mathrm{U}_{1i}\mathrm{Time}_{ti} \times \mathrm{Sex}_i$ represents sex differences in trends, $\mathrm{U}_{1i}\mathrm{Time}_{ti}$ and U_{0i} represent repeated measures, and e_{ti} is the within-subject error term.

Results showed the expected finding that PSAI scores differed between the sexes, $t(5{,}441) = 89.25$, $p < .001$. The overall mean for boys was 62.15 ($N = 2{,}705$), and for girls, the overall mean was 37.68 ($N = 2{,}738$). In addition, there was a significant overall trend in PSAI scores over time for boys and girls combined, $t(5{,}442) = 38.16$, $p < .001$. The mean trend was −0.47 ($N = 5{,}443$) indicating a tendency for children overall to show less male sex-typed behavior (i.e., more female sex-typed behavior) as they grow older. However, this trend differed significantly between the sexes, $t(5{,}441) = 42.99$, $p < .001$, with a mean for boys of 1.98 ($N = 2{,}705$) and a mean for girls of −2.89 ($N = 2{,}738$), demonstrating that the trends for boys and girls were markedly different. Having established that boys and girls showed different means and trends in PSAI scores, MLM analyses were conducted separately for each sex.

The model fitted separately for boys and girls was:

$$\mathrm{PSAI}_{ti} = \gamma_{00} + \gamma_{10}\mathrm{Time}_{ti} + \mathrm{U}_{0i} + \mathrm{U}_{1i}\mathrm{Time}_{ti} + e_{ti}$$

Where PSAI_{ti} is the PSAI score of Child 1 at time t, γ_{00} = is the grand intercept, $\gamma_{10}\mathrm{Time}_{ti}$ is the grand slope, $\mathrm{U}_{1i}\mathrm{Time}_{ti}$ represents repeated measures, and e_{ti} is the within-subject error term.

For boys, the analysis gave a −2 restricted log likelihood of 54,838.9, with an average PSAI score of 60.18 at age 2.5, and a statistically significant average trend of 1.98, $t(2{,}704) = 24.57$, $p < .001$, indicating an increase in male sex-typed behavior over time. A log likelihood is the standard statistic for fitting maximum likelihood in multilevel models, although here we are not reporting the likelihood of alternative models of fit for these data. Estimation of the covariance parameters also showed a significant variation among boys in trends over time (Wald $Z = 11.55$, $p < .001$), showing that the sex-typed behavior of some boys changed more than others. For girls, the −2 restricted log likelihood was 56,179.9, with an average PSAI score of 40.58 at age 2.5, and a statistically significant average trend of −2.89, $t = (2{,}737) = -34.83$, $p < .001$, indicating an increase in female sex-typed behavior over time. Estimation of the covariance parameters showed a significant variation among girls in trends over time (Wald $Z = 10.75$, $p < .001$), showing that the sex-typed behavior of some girls changed more than others. To test the hypothesis that the degree of change in sex-typed behavior differed between the sexes, the trajectory scores derived for each child were reversed for girls (to compare the degree of sex typing rather than the degree of change) and a t test carried out, $t(5{,}442) = -21.53$, $p < .001$, indicating that girls showed a greater change in the direction of sex-typical behavior between the ages of 2.5 and 5 years than did boys.

In order to examine the nature of the relationship between PSAI scores and PSAI trajectories for boys and girls, PSAI scores at age 3.5 were binned (put into categories) at PSAI score intervals of 5 to generate nine categories of PSAI scores for boys and girls separately. PSAI at age 3.5, representing the middle value, that is, the pivotal point, was used rather the mean of the three PSAI scores, in order to retain the statistical parameters of the MLM model. One-way analyses of variance were then carried out with the PSAI trajectory as the dependent variable and the PSAI bin as the independent variable, $F(8, 2696) = 11.25$, $p < .001$, for boys, and $F(8, 2729) = 65.57$, $p < .001$, for girls. Polynomial contrasts were then carried out. For both boys and girls, statistically significant linear effects were found: boys, $F(1, 2696) = 61.04$, $p < .001$; girls, $F(1, 2729) = 407.92$, $p < .001$. Boys with high (i.e., more masculine) PSAI scores at age 3.5 showed significantly more change over time than boys with low (i.e., less masculine) PSAI scores (see Table 2). Similarly, girls with low (i.e., more feminine) PSAI scores at age 3.5 changed significantly more over time than girls with high (i.e., less feminine) PSAI scores (see Table 3). Thus, the children who were most sex typed to start with became even more so over time. Means and standard deviations of the trajectory scores at the various levels of PSAI scores at age 3.5 appear in Figures 1 and 2 for boys and girls, respectively. The relationship between the PSAI at age 3.5 and the CAI at age 8 was also examined for boys and girls separately. One-way analyses of variance were carried out with the CAI as the dependent variable and the PSAI bin as the independent variable. Significant effects were found for both boys, $F(8, 2696) = 7.08$, $p < .001$, and girls, $F(8, 2729) = 16.08$, $p < .001$. Polynomial contrasts were applied and statistically significant linear effects were found for boys, $F(1, 2696) = 31.52$, $p < .001$, and girls, $F(1, 2729) = 89.92$, $p < .001$. Boys with high (i.e., more masculine) PSAI scores at age 3.5 showed significantly higher CAI scores at age 8 than boys with low (i.e., less masculine) PSAI scores at age 3.5 (see Table 4 and Figure 3). Similarly, girls with low (i.e., more feminine) PSAI scores at age 3.5 showed lower CAI scores at age 8 than girls with high (i.e., less feminine) PSAI scores at age 3.5 (see Table 5 and Figure 4). Thus, the children who were most sex typed at age 3.5 continued to be so at age 8.

In order to examine the nature of the relationship between PSAI trajectory scores and CAI scores for boys and girls, that is, whether the rate of change in PSAI scores predicted CAI scores at age 8, PSAI trajectory scores were binned at intervals of 1.00 to generate eight categories of PSAI trajectory scores for boys and girls separately. One-way analyses of variance were then carried out with the CAI score as the dependent variable and the PSAI trajectory bin as the independent variable. Significant effects were found for both boys, $F(7, 2697) = 3.29$, $p < .002$, and girls, $F(7,$

2730) = 17.63, $p < .001$. Polynomial contrasts were then carried out. Statistically significant linear effects were found for boys, $F(1, 2697) = 15.01, p < .001$, and girls, $F(1, 2730) = 77.30, p < .001$. Boys with higher PSAI trajectory scores (i.e., those who showed the greatest increase in masculinity) showed significantly higher levels of male sex-typed behavior at age 8 than boys who showed relatively less increase (see Table 6 and Figure 5). Similarly, girls with lower PSAI trajectory scores (i.e., those who showed the greatest increase in femininity) showed significantly higher levels of female sex-typed behavior at age 8 than girls who showed relatively less decrease (see Table 7 and Figure 6). For girls, but not for boys, a significant quadratic effect was also found, $F(1, 2730) = 13.10, p < .001$, indicating that girls who showed no increase in sex-typed behavior between the ages of 2.5 and 5 years showed the least feminine sex-typed behavior at age 8. These girls obtained CAI scores at age 8 that fell halfway between the average score for girls and the average score for boys. Thus, the children who showed the greatest increase in sex typing from 2.5 to 5 years old were the most sex typed at age 8, and the girls who showed no change in sex-typed behavior between age 2.5 and age 5 showed undifferentiated sex-typed behavior at age 8.

A step-down regression was then carried out to determine whether the PSAI trajectory added any

predictive power to the PSAI score at age 3.5 in estimating CAI scores at age 8 (again separately for boys and girls). For boys, the multiple correlation showed a statistically significant increase from .134 to .152 ($p < .001$). For girls, the multiple correlation showed a statistically significant increase from .199 to .236 ($p < .001$). These findings show that the combination of the PSAI score at age 3.5 and the PSAI trajectory from 2.5 to 5 years was a better predictor of CAI score at age 8 for both boys and girls than either measure alone.

Discussion

The findings of this longitudinal study of a general population sample not only show that children's sex-typed behavior increases through the preschool years but also that those children who were the most sex typed at age 2.5 are still the most sex typed at age 5, with girls showing a greater increase in sex-typed behavior over time than boys. In addition, those children who showed the highest levels of sex-typed behavior during the preschool years continued to do so at age 8, as assessed by a modified self-report version of the PSAI. Thus, it appears that sex-typed toddlers grow up to be sex-typed children, that is, that sex-typed behavior remains stable over time, at least from ages 2.5 to 8 years.

Instead of the usual question "What causes children of the opposite sex to differ in their behavior?" the findings of the present study address the rather different question "What causes children of the same sex to show variation in sex-typed behavior that is

apparent from an early age, intensifies over time, and remains stable from toddlerhood to middle childhood?" From a biological perspective, it could be argued that variation in prenatal androgen levels predispose some children within each sex to be more sex typed than others. The role of androgens in gender development has been studied in children exposed to atypical levels prenatally, with higher levels of testosterone associated with more male-typical toy, playmate, and activity preferences, as well as temperamental characteristics (Berenbaum & Hines, 1992; Dittmann et al., 1990; Hines & Kaufman, 1994; Pasterski et al., 2007). In a study of children in the current sample at age 3.5, an association was found between maternal testosterone concentrations during pregnancy and degree of sex-typed behavior in girls (Hines et al., 2002). Because prenatal androgen exposure is thought to influence subsequent sex-typed behavior by permanent alterations in brain development (Arnold & Gorski, 1984; De Vries & Simerly, 2002), individual variability in prenatal testosterone exposure could cause permanent neural alterations that contribute to continuity in sex-typical behavior over time. Although this explanation could account for the onset of behavioral preferences and their maintenance, it would not explain the increase we observed in sex-typed behavior with age.

Social learning and cognitive developmental explanations of behavioral differences between the sexes may also be relevant to understanding the mechanisms involved in variation in sex-typed behavior within each sex and to the increase in sex-typed behavior over time. The differential reinforcement of sex-typed behavior in boys and girls, and the extent to which children are exposed to sex-typed models, may both be implicated, such that children who experience high levels of reinforcement for sex-typed behavior, and whose role models are highly sex typed, may exhibit higher levels of sex-typed behavior themselves. Similarly, individual differences in gender schematization, that is, in the selective processing of gender-related information (Levy & Carter, 1989), and in gender labeling (Martin, Ruble, & Szkrybalo, 2002), may also play a part in within-sex variation in sex-typed behavior. Insofar as the mechanisms described by social learning and cognitive developmental theorists continue through childhood, it might be expected that their influence on children's sex-typed behavior would increase over time.

The prediction of a greater increase in sex-typed behavior by those who were most extreme to start with was also confirmed. This is of particular interest as the phenomenon of regression to the mean would lead to the opposite prediction, that is, to the prediction that those who were most extreme to start with would show the greatest decrease in sex-typed behavior over time. An explanation for our finding is that the acquisition of sex-typed behavior involves a series of interacting processes such that children who are biologically predisposed to show higher levels of sex-typed behavior as toddlers experience greater exposure to social and psychological influences that are likely to increase sex-typed behavior even further as they grow up. For example, gender segregation and the differences in play styles experienced by boys and girls in same-sex peer groups (Maccoby, 1998) may be involved, such that children who show higher levels of sex-typed behavior at the outset may be more likely to play with children of the same sex and thus be more likely to engage in sex-typed behavior. As a result, sex-typed toddlers may become even more sex-typed through childhood. Our finding that the PSAI score at age 3.5 in combination with the PSAI trajectory from 2.5 to 5 years was a better predictor of CAI score at age 8 than either measure alone supports this perspective. Further evidence for this explanation comes from the findings of Martin and Fabes (2001), who demonstrated that playing with same-sex peers directly increased sex-typed behavior over and above individual tendencies to do so. It is not clear why highly sex-typed girls show a greater increase in sex-typed behavior as they grow older than do highly sex-typed boys. However, Martin and Fabes have argued that girls' groups experience greater socialization pressures from adults than do boys' groups, which may account for the greater increase in the sex-typed behavior of highly sex-typed girls than in the sex-typed behavior of highly sex-typed boys found in the present study.

The present study is the first to follow up a large number of children from toddlerhood to middle childhood to examine the development of sex-typed behavior over time. Particular advantages of the investigation were the involvement of a general population sample of boys and girls at four time points ranging from 2.5 to 8 years and the use of an assessment instrument specifically designed to assess within-sex variation in sex-typed behavior. The findings demonstrate that the degree of sex-typed behavior exhibited by boys and girls early in life is a good indicator of their degree of sex-typed behavior as they grow up, that sex-typed behavior increases between toddlerhood and middle childhood for both boys and girls, and that divergence between sex-typical and sex-atypical children increases as they progress through childhood, particularly among girls. Our findings argue for the importance of social-cognitive processes in elaborating early sex-typed behavior, perhaps building on early tendencies set in place by the prenatal hormonal environment.

Developmental Psychology Lecturer

Department of Psychology, Auckland
Vacancy Number A173-08L

The Department of Psychology invites applications for a tenure-track Lecturer/Senior Lecturer in Developmental Psychology. Applicants should have a PhD in Psychology and the qualifications necessary to teach Developmental Psychology at both undergraduate and postgraduate levels. You should also have a proven record of research and be able to supervise post graduate students. The Department is one of the largest in New Zealand, with 920 equivalent full-time students, 40 permanent academic staff and 10 administrative and technical support staff. The Department offers Bachelor, Honours, Masters and PhD degrees in Psychology and postgraduate qualifications in professional psychology.

Ideally, the role will start 1 February 2009.

Applications close Friday, 31 October 2008.

For further information contact Associate Professor Fred Seymour, Head of Department of Psychology on +64 9 373 7599 ext 88414, or email f.seymour@auckland.ac.nz.

The department's website is www.psych.auckland.ac.nz.

Please apply online at www.opportunities.auckland.ac.nz.

Notice to Contributors

Child Development publishes empirical, theoretical, review, applied, and policy articles reporting research on child development. Published by the interdisciplinary Society for Research in Child Development (SRCD), the journal welcomes relevant submissions from all disciplines. Further information is available at http://www.srcd.org/cd.html.

Types of Articles

Child Development considers manuscripts in formats described below. Inquiries concerning alternative formats should be addressed to the Editor prior to submission. All submissions are expected to be no more than 40 manuscript pages, including tables, references, and figures (but excluding appendices). Authors should provide a justification if the submission is substantially longer. Unless the editor finds that justification compelling, the submission will be returned to the author for shortening prior to editorial review.

Empirical articles comprise the major portion of the journal. To be accepted, empirical articles must be judged as being high in scientific quality, contributing to the empirical base of child development, and having important theoretical, practical, or interdisciplinary implications. Reports of multiple studies, methods, or settings are encouraged, but single-study reports are also considered. Empirical articles will thus vary considerably in length, but should be no longer than 40 manuscript pages; text and graphics should be as concise as material permits. All modes of empirical research are welcome.

Empirical reports are reserved for short cutting-edge empirical papers that are no longer than 4,000 words in length (including text, tables, footnotes, appendices), which advance research and knowledge in an area through noteworthy findings and/or new methods. For manuscripts that require longer descriptions of methods and results, authors should use the Empirical article format.

Reviews focus on past empirical and/or on conceptual and theoretical work. They are expected to synthesize or evaluate a topic or issue relevant to child development, should appeal to a broad audience, and may be followed by a small number of solicited commentaries.

Essays describe original concepts, methods, trends, applications, and theories; these may also be accompanied by solicited commentaries.

Child Development and ... are articles that provide readers with tutorials about some new concept or academic specialty pertinent to research in child development. These papers should review the major definitions, methods, and findings of the concept or specialty and discuss past or potential links to child development.

From another perspective is a format in which papers on a focal topic, written by different authors, are published simultaneously. Papers represent diverse perspectives (e.g., authors whose work represents different populations; different disciplines; different theories, methods, or analytic tools). In some cases, calls for submissions on particular topics will be disseminated through SRCD (via e-mail or SRCD publications), and submissions will undergo normal editorial review. In some cases, a submitted manuscript (e.g., an empirical article) may be selected as a lead article for this format, with invited commentaries providing additional perspectives. The editors also welcome suggestions from readers for topics for this format.

Manuscript Submission

Child Development invites for consideration manuscripts that are neither identical to nor substantially similar to work published or under review elsewhere. In the submission cover letter, please provide details about other published or submitted papers having substantial overlap (including data sets) with the new CD submission to enable editors to judge whether the new submission is sufficiently distinct from other work to warrant consideration. Please note if the paper is posted on a website, see http://www.srcd.org/webposting.html. Editors retain the right to reject manuscripts that do not meet established ethical standards for research or dissemination.

Manuscripts should be submitted electronically to the Child Development Online Submission Site at www.srcd.org/CDsubmit/ as a Word or WordPerfect file. Please also submit a cover letter that contains the name(s) of the author(s) and affiliation(s), and the street address, telephone, fax, and electronic mail address of the corresponding author. A corresponding author's submission to *Child Development* implies that all co-authors have agreed to the content and form of the manuscript and that the ethical standards of SRCD have been followed (see the *Child Development* website or pp. 283–284 of the 2000 SRCD Directory). Any financial interest or conflict of interest must be explained to the Editor in the cover letter. The corresponding author is responsible for informing all coauthors, in a timely manner, of manuscript submission, editorial decisions, reviews, and revisions. Please note that if your submission (or its revision) is accepted for publication, each author must submit a signed Exclusive License Form (http://www.srcd.org/Documents/Publications/CD/cdcopyright.pdf) before the manuscript can enter production. Planning ahead to meet this requirement is especially important for manuscripts with multiple authors.

The manuscript file should be formatted with double-spaced, 12-point type, and should include a single paragraph abstract of 100–120 words. Please follow all guidelines on format, style, and ethics provided in the Publication Manual (5th ed.) of the American Psychological Association. Figures included with initial submissions will not be returned. Therefore, please submit only electronic files or copies of figures. Authors should keep a copy of all correspondence, files, and figures to guard against loss.

Manuscript Review

If you have any questions about your submission, please inquire at cdev@srcd.org or call (734) 926-0615. Each manuscript is handled by the Editor or an Associate Editor who consults with one or more Consulting Editors and/or ad hoc reviewers who have relevant expertise. To ensure blind review, cover sheets are removed before review; authors should avoid including any other information about identity or affiliation in submissions. Copies of the submission and associated correspondence are retained in the SRCD archives. For accepted manuscripts, authors are required to prepare a 300–500 layperson's summary for public dissemination purposes. Details are provided to authors as part of final processing.

There is no charge for publication in *Child Development* unless tabular or graphic materials exceed 10% of the total number of pages. Charges are also levied for changes in proofs other than correction of printer's errors. Any inquiries relating to charges or business matters (including reprint orders) should be addressed to Wiley-Blackwell, *Child Development*, Production Coordinator, 350 Main Street, Malden, MA 02148, (781) 388-8200.

Inquiries and suggestions regarding editorial policy may be addressed to: Dr. Jeffrey J. Lockman, Incoming Editor, Department of Psychology, Tulane University, 2007 Percival Stern Hall, New Orleans, LA 70118-5698, lockman@tulane.edu. *Please do not send electronic or paper manuscripts to the above address.* Doing so will delay the processing of your manuscript.

Understanding Mother-Adolescent Conflict Discussions: Concurrent and Across-Time Prediction From Youths' Dispositions and Parenting—*Nancy Eisenberg, Claire Hofer, Tracy L. Spinrad, Elizabeth T. Gershoff, Carlos Valiente, Sandra Losoya, Qing Zhou, Amanda Cumberland, Jeffrey Liew, Mark Reiser, and Elizabeth Maxon* (Serial No. 290, 2008)

Developing Object Concepts in Infancy: An Associative Learning Perspective—*David H. Rakison and Gary Lupyan* (Serial No. 289, 2008).

The Genetic and Environmental Origins of Learning Abilities and Disabilities in the Early School Years—*Yulia Kovas, Claire M. A. Haworth, Philip S. Dale, and Robert Plomin* (Serial No. 288, 2007).

The Preservation of Two Infant Temperaments Into Adolescence—*Jerome Kagan, Nancy Snidman, Vali Kahn, and Sara Towsley* (Serial No. 287, 2007).

Children's Questions: A Mechanism for Cognitive Development—*Michelle M. Chouinard* (Serial No. 286, 2007).

Best Practices in Quantitative Methods for Developmentalists—*Kathleen McCartney, Margaret R. Burchinal, and Kristen L. Bub* (Serial No. 285, 2006).

Foundations of Self-Awareness: An Exploration Through Autism—*R. Peter Hobson, Gayathri Chidambi, Anthony Lee, and Jessica Meyer* (Serial No. 284, 2006).

Our Children Too: A History of the Black Caucus of the Society for Research in Child Development, 1973–1997—*Diana T. Slaughter-Defoe, Aline M. Garrett, and Algea O. Harrison-Hale* (Serial No. 283, 2006).

Parental Support, Psychological Control, and Behavioral Control: Assessing Relevance Across Time, Culture, and Method—*Brian K. Barber, Heidi E. Stolz, and Joseph A. Olsen* (Serial No. 282, 2005).

Being Hurt and Hurting Others: Children's Narrative Accounts and Moral Judgments of Their Own Interpersonal Conflicts—*Cecilia Wainryb, Beverly A. Brenl, and Sonia Matwin* (Serial No. 281, 2005).

Childhood Sexual Assault Victims: Long-Term Outcomes After Testifying in Criminal Court—*Jodi A. Quas, Gail S. Goodman, Simona Ghetti, Kristen Weede Alexander, Robin Edelstein, Allison D. Redlich, Ingrid M. Cordon, and David P. H. Jones* (Serial No. 280, 2005).

The Emergence of Social Cognition in Three Young Chimpanzees—*Michael Tomasello and Malinda Carpenter* (Serial No. 279, 2005).

Trajectories of Physical Aggression From Toddlerhood to Middle Childhood: Predictors, Correlates, and Outcomes—*NICHD Early Child Care Research Network* (Serial No. 278, 2004).

Constraints on Conceptual Development: A Case Study of the Acquisition of Folkbiological and Folksociological Knowledge in Madagascar—*Rita Astuti, Gregg E. A. Solomon, and Susan Carey* (Serial No. 277, 2004).

Origins and Early Development of Human Body Knowledge—*Virginia Slaughter, Michelle Heron, Linda Jenkins, and Elizabeth Tilse* (Serial No. 276, 2004).

Mother – Child Conversations About Gender: Understanding the Acquisition of Essentialist Beliefs—*Susan A. Gelman, Marianne G. Taylor, and Simone P. Nguyen* (Serial No. 275, 2004).

The Development of Executive Function in Early Childhood—*Philip David Zelazo, Ulrich Müller, Douglas Frye, and Stuart Marcovitch* (Serial No. 274, 2003).

Personal Persistence, Identity Development, and Suicide: A Study of Native and Non-native North American Adolescents—*Michael J. Chandler, Christopher E. Lalonde, Bryan W. Sokol, and Darcy Hallett* (Serial No. 273, 2003).

Personality and Development in Childhood: A Person-Centered Approach—*Daniel Hart, Robert Atkins, and Suzanne Fegley* (Serial No. 272, 2003).

How Children and Adolescents Evaluate Gender and Racial Exclusion—*Melanie Killen, Jennie Lee-Kim, Heidi McGlothlin, and Charles Stangor* (Serial No. 271, 2002).

Child Emotional Security and Interparental Conflict—*Patrick T. Davies, Gordon T. Harold, Marcie C. Goeke-Morey, and E. Mark Cummings* (Serial No. 270, 2002).

The Developmental Course of Gender Differentiation: Conceptualizing, Measuring, and Evaluating Constructs and Pathways—*Lynn S. Liben and Rebecca S. Bigler* (Serial No. 269, 2002).

The Development of Mental Processing: Efficiency, Working Memory, and Thinking—*Andreas Demetriou, Constantinos Christou, George Spanoudis, and Maria Platsidou* (Serial No. 268, 2002).

Child Development

CHILD DEVELOPMENT (ISSN 0009-3920), one of three publications of the Society for Research in Child Development, Inc., is published bimonthly by Wiley Subscription Services, Inc., a Wiley Company, 111 River St., Hoboken, NJ 07030-5774. Periodical Postage Paid at Hoboken, NJ and additional offices.

Postmaster: Send all address changes to *CHILD DEVELOPMENT*, Journal Customer Services, John Wiley & Sons Inc., 350 Main Street, Malden, MA 02148-5020.

Information for Subscribers: *Child Development* is published in six issues per year. Subscription prices for 2008 are: Premium Institutional: US$585 (The Americas), £417 (Rest of World). Premium Online-Only rates are also available (see below). Prices are exclusive of tax. Australian GST, Canadian GST and European VAT will be applied at the appropriate rates. For more information on current tax rates, please go to www.wiley.com, click on Help and follow the link through to Journal subscriptions. The Premium institutional price includes online access to the current and all online back files to January 1st 1997, where available. For other pricing options, including access information and terms and conditions, please visit www.interscience.wiley.com/journals.

Delivery Terms and Legal Title: Prices include delivery of print journals to the recipient's address. Delivery terms are Delivered Duty Unpaid (DDU); the recipient is responsible for paying any import duty or taxes. Legal title passes to the customer on despatch by our distributors.

For more information about Wiley-Blackwell journals, including online access information, terms and conditions, and other pricing options, please visit www.blackwellpublishing.com or contact our customer service department, tel: (800) 835-6770 or +1 (781) 388-8598 (US office); +44 (0) 1865 778315 (UK office); or +65 6511 8000 (Asia Office). Subscription in 2008 includes three issues of *Monographs of the Society for Research in Child Development* and three issues of *Child Development Perspectives*. Single issues from current and recent volumes are available at the current single issue price from Wiley-Blackwell Journals. Earlier issues may be obtained from Periodicals Service Company, 11 Main Street, Germantown, NY 12526, USA. Tel: +1 518 537 4700, Fax: +1 518 537 5899, Email: psc@periodicals.com. Volumes 37 to date are available in microfilm from ProQuest Information and Learning, Serials Customer Service Department, 300 North Zeeb Road, Ann Arbor, MI 48106; telephone: (800) 521-0600 x2873.

Electronic Access: The *Child Development* website can be found at www.srcd.org/cd.html. Abstract information for this journal is electronically available at www.blackwellpublishing.com/cdev. This journal is available online at Wiley InterScience. Visit www3.interscience.wiley.com to search the articles and register for table of contents e-mail alerts.

For new orders, renewals, sample copy requests, claims, changes of address and all other subscription correspondences please contact the Journals Department at your nearest Wiley-Blackwell office (address details listed above). UK office phone: +44 (0) 1865-778315, Fax: +44 (0) 1865-471775, Email: cs-journals@wiley.com; US office phone: 800-835-6770 or 781-388-8598, Fax: 781-388-8232, Email: cs-journals@wiley.com; Asia office phone: +65 6511 8000, Fax: +44 (0) 1865-471775, Email: cs-journals@wiley.com.

Reflections on Child Development: The Journal and the Field

Lynn S. Liben
The Pennsylvania State University

One of the privileges of serving as editor of *Child Development* (*CD*) is the chance to write two editorials—one as one begins one's editorship and another as one departs.

My first editorial was filled with a sense of excitement and opportunity. My comments were focused primarily on the journal itself, what it offered, what I hoped it would continue to offer, and how I hoped it might be changed, ever so slightly, to achieve some additional goals.

Although I am perhaps too close to provide an unbiased appraisal, the journal appears to have continued on a strong trajectory. Among the signs of the journal's continued health and development have been annual increases in the numbers of article submissions (despite growing numbers of competing journals), expanded media coverage of *CD* research (traceable to the press releases prepared by the Office of Policy and Communication based on the layperson summaries now required from *CD* authors), the documented high volume of online use of articles (including many of the articles and commentaries in special collections such as the special issue on *Race, Ethnicity, and Culture in Child Development* and the *From Another Perspective* collections on the effects of day care and on emotion regulation), the initiation and refinement of streamlined and user-friendly submission and review procedures (about which we often received unsolicited praise), and data from citation indices showing *CD*'s persistent high impact in a number of fields (e.g., developmental and educational psychology).

I am more than happy to take credit for navigating the journal along this positive trajectory, but in truth, it has been a collective effort. Thus, I would like to take this opportunity to thank, again, all those who have worked with me over the past 6 years as associate editors, managing editors, production editors, consulting editors, and ad hoc reviewers, and to thank the many other staff members, Society for Research in Child Development (SRCD) officers, and SRCD committee members who have been essential to the operation of *CD*. This is not an editorship that one can do alone.

My comments so far all concern the journal itself. But the editor of *CD* also has reason to reflect on the field more broadly. The person in this role is often asked about trends in the field, about the latest discoveries, and about continuing controversies. It is on these broader issues of developmental scholarship that I have chosen to focus the remainder of my final editorial.

It is perhaps a metaphor that can best capture my view of the field and where it has traveled over time, including over the half dozen years of my editorial term. The metaphor I would select is the glass—both half full and half empty.

One way to see the optimistic version of the glass is to read with contemporary eyes the articles that appeared in *CD* during 1930, the first year of the journal's publication. This is an exercise I often assign in teaching, but I suspect that it is one even more illuminating for experienced scholars than it is for novices. The reader of the 21st century is struck by the limited scope of those early articles, by their greater reliance on what we would now characterize as unreliable and subjective observational and coding systems, by their small samples, by their unsophisticated and primarily descriptive statistics, and, not surprisingly given the relative infancy of the field, by their more restricted links to theoretical positions and other empirical findings.

In the roughly 75 years that have elapsed since those first issues of *CD* appeared, the field of child development has grown exponentially, adding content and theory, and, especially, method. Observational systems are better documented, more detailed, and reliable; technological advances allow the measurement of biological variables or events that were earlier unobservable or perhaps even unimaginable; and statistical methods and the associated computer technology to implement them have provided new ways to generate and evaluate complex models and experimental effects.

To illustrate how far the field has come methodologically, consider Myrtle McGraw's (1935) classic

---

study on the effects of physical exercise on infant development. Using a cotwin design to hold genetic endowment constant, she gave Johnny—but not Jimmy—a special exercise regimen and compared the two boys' motor outcomes. It seems almost quaint to read that the categorization of the twins as monozygotic was based solely on their having shared a single placenta. As is often forgotten when the classic Johnny and Jimmy work is discussed, there were later indications that the brothers were not, in fact, monozygotic twins: "After the twins were older, study by the resemblance method cast doubt upon their single-ovum origin. . . . The differences in personal appearance have become more noticeable as the children have grown older" (McGraw, 1935, p. 33). Without question, contemporary genetic research has devised far stronger methods with which to test individuals' genetic material. It is not only measures of biological qualities that have improved. Even in the short span of my own editorship, the field has shown an increased range of topics, ever more sophisticated methods for collecting and analyzing data, increased interdisciplinarity, greater attention to diversity, and enhanced attention to the application of scholarly contributions to the lives of children as they develop in families, schools, and community.

Lest the field become too self-congratulatory, however, it is equally important to recognize that the glass remains half empty as well. Today's readers of those early issues of *CD* are also likely to be struck by the almost uncanny similarity between the questions asked then and now. Skeptical readers might find themselves wondering whether we have, in fact, made any progress at all. If one compares an article on a particular topic from an early issue to one on the same general topic in a recent issue (another teaching exercise I often employ), one is often struck by remarkably similar questions with remarkably similar and still only tentative, incomplete answers.

An important question that emerges from these historical contrasts is whether our field is as cumulative a science as it might be. As the editor of *CD*, I have seen a large number of articles describing a wide variety of research projects on a disparate range of topics using a diversity of methods. This experience has only reinforced an observation that I made roughly a decade ago (Liben, 1997) concerning the incomplete grounding of much contemporary work in past scholarship. That is, theories and findings whose core points appeared many decades ago are proposed, *de novo*, today. Contemporary investigators often appear to be unaware of an earlier version of their "new" idea, particularly when the vocabulary used to label it differs. This observation on the state of the field is neither unique to me nor is it applicable to only the recent past. For example, Cairns and Ornstein (1979) made a related point in a historical review of developmental psychology. In the course of discussing James Mark Baldwin, they said: "It is an irony in the history of developmental thought that one of its most brilliant originators is, today, virtually unknown and unrecognized. The irony lies, of course, in the presumed commitment of developmental theory to historical processes while neglecting its own scientific history" (pp. 470–471). Even earlier, Kessen (1965) commented on the field's historical neglect, saying: "The history of child study is a history of rediscovery. With remarkable regularity, the same themes appear, are elaborated for a while, then fade" (p. 1).

One means of assessing the influence of older work on contemporary scholarship is to examine the citation of earlier work in current articles. A tally of the references included in the most recent issue of *CD* available at the time this editorial was written (volume 79, issue 4) revealed that of the 1,259 references contained within 23 articles, only 4 referred to publications prior to 1960, 17 were drawn from the 1960s, and 66 from the 1970s. The remaining 1,172 reference entries were from the 1980s ($n = 223$), 1990s ($n = 437$), and 2000s ($n = 512$).

It is not, however, only that older theories and empirical work are often overlooked in contemporary literature. It is also that they are often distorted. Sometimes distortions appear to evolve as a result of using successive secondary or tertiary sources rather than consulting primary sources (for a well-documented illustration, see Harris, 1979). Sometimes distortions appear to occur as the result of erecting theoretical straw men (Liben, 1997) that—although potentially useful for clarifying hypothetical alternatives—may misrepresent constructs and the metatheoretical bases of the arguments (Overton, 2006). Whatever the reason, earlier work that is either forgotten or distorted does not provide a solid foundation on which to build incremental knowledge.

The importance of building on prior accomplishments is, of course, well appreciated in science. A phrase commonly attributed to Sir Isaac Newton (see Merton, 1985/1965) captures this notion well: "If I have seen farther, it is by standing on the shoulders of giants." I would not be the first to suggest that our field does not do this as well as it might. In one particularly dramatic statement, Zeaman (1959) compared the natural and social sciences by suggesting that "in the natural sciences, each succeeding generation stands on the shoulders of those that have gone before, while in the social sciences, each generation steps in the face of its predecessors" (p. 167). As Cairns and Ornstein (1979) noted, there is indeed irony in a developmental field that fails to build on its own developmental roots.

To leave the shoulders of giants and return to the metaphorical glass, what can be done to fill the glass of *CD* yet higher? Consistent with the evaluation offered initially with respect to the trajectories of the journal and the field, one obvious strategy is to continue to add to the corpus of high-quality work. Consistent with the argument that historical contributions are often not attended to sufficiently, a second strategy is to promote more and closer attention to earlier scholarship, even as investigators simultaneously break new ground. Consistent with the argument that earlier work is often distorted or misunderstood, a third strategy is to encourage careful readings that include attention to primary sources and to metatheoretical issues. It is not only to honor our intellectual forbearers. It is also to benefit from them and to increase the cumulative nature of developmental science.

In closing my final editorial, I would like to leave the lofty realm of pronouncements for the entire field and return to a more personal level. I ended my initial editorial 6 years ago by likening the editorship of *CD* to owning a Patek Philippe watch, about which it is said, "You never actually own a Patek Philippe. You merely take care of it for the next generation." I began my term by saying that I was honored to have been entrusted with this scholarly jewel. As I finish my term, I am relieved to report that the watch is still ticking, that I have very much enjoyed wearing it, and that I am looking forward to the feel of the breeze on my bare wrist.

Continuities and Discontinuities in Children and Scholarship

Lynn S. Liben
The Pennsylvania State University

This article introduces a collection of essays on continuity and discontinuity in cognitive development. In his lead essay, J. Kagan (2008) argues that limitations in past research (e.g., on number concepts, physical solidarity, and object permanence) render conclusions about continuity premature. Commentaries respectively (1) argue that longitudinal contexts are essential for interpreting developmental data, (2) illustrate the value of converging measures, (3) identify qualitative change via dynamical systems theory, (4) redirect the focus from states to process, and (5) review epistemological premises of alternative research traditions. Following an overview of the essays, this introductory article discusses how the search for developmental structures, continuity, and process differs between mechanistic-contextualist and organismic-contextualist metatheoretical frameworks, and closes by highlighting continuities in Kagan's scholarship over the past half century.

In his essay, "In Defense of Qualitative Changes in Development," Kagan (2008) addresses a contemporary controversy: Are the cognitive functions seen in infancy preserved into and beyond childhood or are they so transformed in ontogenesis that they should be viewed as qualitatively different functions? Kagan mounts an argument for the need for caution in the resolution of this debate. The five commentaries address Kagan's points and offer additional arguments and empirical data bearing on the continuity–discontinuity issue. Taken together, the articles demonstrate the diverse ways that developmental scientists conceptualize, empirically study, and draw conclusions about continuous versus qualitative change.

Delineating the Questions

Kagan (2008) observes that scientists from a number of disciplines take as their primary goal "to explain how a phenomenon of interest developed its observed form" (p. 1606). He illustrates his point by drawing from evolutionary biology, embryology, and, his focus here, developmental psychology. After providing some historical perspective on prevailing developmental beliefs of earlier eras, Kagan critiques the currently popular view that individual development is best characterized as quantitative rather than qualitative change. Typical of such accounts are nativist theories and research programs that imbue infants with an assortment of underlying and fundamentally adult-like competencies that need merely to be triggered and sharpened by contact with the world. Kagan notes that the theoretical and empirical claims for preservation of function from infancy to maturity have been offered in two major arenas of contemporary developmental psychology, one the preservation or continuity of early emotional attachment, the other the preservation or continuity of early cognitive functions. It is the second of these he addresses in the core of his article.

Kagan identifies two major problems with contemporary research programs that promulgate cognitive continuity. The first concerns language. Kagan argues that too often identical labels are used for behaviors that might, on the surface, appear identical, but that, at root, might be distinct. One illustration he gives is the use of the term *imitation* to label an infant's tongue protrusion in the presence of an adult's tongue protrusion. In the neonate, protrusions might reflect infants' tendencies to use their tongues to explore nearby objects; in the older infant, they might indicate infants' representation-based copying of another person's behavior. Applying the identical term—*imitation*—to both earlier and later instantiations of an observable behavior, "tempts less sophisticated readers to assume that the two phenomena are exemplars of the same process" (p. 1607). Kagan thus urges the use of different terminology for cognitive functions that are what he calls schematic (containing only perceptually available information) from those he calls semantic (containing additional, based

---

I am grateful to Michael Chandler and Willis Overton for their thoughtful comments on an earlier draft of this article.

information as well). Of course, just as someone wishing to leave room for qualitative change may argue that identical labels for earlier versus later behaviors are misleading, so, too, someone arguing for continuity may argue that *different* labels are misleading. Despite the possible legitimacy of both positions, the former arguably has more traction because—as in any coding system—one can collapse categories later, but one cannot recover distinctions that were initially ignored. Even then, though, one would still be left with the dilemma of deciding—in the absence of agreement about what underlies any given observable behavior or how to differentiate one observable behavior from another—when to apply which label.

Kagan's second major critique revolves around the empirical database that he claims is far too weak to support conclusions about infants' cognitive functions that are routinely drawn by contemporary investigators. Kagan, like others before him (e.g., Haith, 1998) faults the field for its heavy reliance on looking time methods. His critique is in part based on the varied bases for looking time per se and in part based on the more general point that converging methods and data are needed in research. Kagan draws from research in three domains—the concept of number, physical solidity, and object permanence—to illustrate his conceptual and methodological points related to continuity and transformation. He ends his article by urging the use of a greater range of measures and greater attention to the role of the maturing brain.

Kagan's Gauntlet

Kagan entitled his article a defense, but more accurately, it is a challenge. Indeed, in the opening sentence of their commentary, Campos et al. (2008) remark that Kagan "has dropped a gauntlet, challenging the major intellectual and empirical trends in infancy research of the past quarter century" (p. 1625). The five commentaries respond to the challenge set before them, albeit in very different ways.

Expanding the Challenge

Campos et al. (2008) violently agree with Kagan. They endorse the need for converging evidence and replications and offer additional examples of overinterpretations of empirical data. The bulk of their commentary is devoted to expanding on Kagan's argument, often linking their points to metatheoretical issues (many of which are addressed explicitly in the final commentary by Müller & Giesbrecht, 2008). Their overriding theme concerns the essential need to embed all developmental research within a longitudinal context. Without it, interpretation of a given behavior at a given age may be misleading. They provide several specific examples of behaviors (e.g., imitation and reaching) that appear to be morphologically identical across age but that are revealed to be qualitatively different once one examines the broader context in which the given action is embedded. They also develop the argument that particular behaviors—even those that serve a function at a particular period of the life span—may or may not have consequences for or connections to later competencies. Behaviors may regress as well as progress. Further, they argue that development need not always consist of new individual functions; it can sometimes represent novel forms that emerge by nonadditive reorganizations of earlier functions. However, as becomes clear both within the current set of commentaries as well as from far more extensive discussions of metatheoretical issues in developmental science (e.g., Overton, 2006, 2007; Witherington, 2007), the centrality and scientific legitimacy of the search for novel, emergent outcomes differs across metatheoretical frameworks.

Accepting the Challenge

Quinn (2008) accepts Kagan's challenge as an empirical challenge. Quinn agrees with Kagan that the findings from many empirical studies with infants have indeed been flawed and overinterpreted. He argues, however, that some investigations do use the kinds of empirical approaches to study infant cognition that Kagan recommends. To illustrate, he selects the example of infant categorization and draws from his program of research to illustrate how research using multiple approaches (e.g., looking times, event-related potentials, computational modeling) converge on the conclusion that category structures of infants (e.g., for cats and dogs) are indeed similar to those of adults. Thus, Quinn makes the case for why, to use Kagan's terminology, schematic categorization may indeed be linked, continuously, to semantic categorization. Interestingly, though, the "structural similarity" of Quinn's illustrative focus is on whether infants' and adults' assignments of animals into cat versus dog categories match. It is not, for example, on whether infants and adults share an understanding of the logical relations between and among categories (e.g., cats, dogs, animals) such as would be taken as a hallmark of classification understanding by Piaget (1952).

Redefining the Challenge

Spencer and Perone (2008) join Kagan in his defense of qualitative change, writing from their explicit commitment to dynamical systems theory (DST). Before assuming highly congruent perspectives, however, it would be wise to remember Kagan's first point about problems stemming from the use of identical words for what may be fundamentally different constructs or behaviors. To Spencer and Perone's credit, they explicitly note the confusion that results from discrepant definitions, and they thus begin their commentary by providing their theory-embedded definition of the term "qualitative." Specifically, and as explained in detail in the commentary, the term qualitative change is used within DST to refer to changes from one stable attractor state to another. One feature of their approach is that the behaviors being modeled are unfolding on the second-to-second timescale. Another is that qualitative transformations (as defined within DST) can emerge from continuous changes. Spencer and Perone argue that the study of qualitative shifts over broad periods of time (as in the years between infancy and childhood) show little about the way behavior in real time is organized. Their approach is thus based on examining tiny units that are intentionally removed from the kinds of analyses and constructs promulgated by Campos et al. (2008; see also Witherington, 2007).

Redirecting the Challenge

Adolph and Robinson (2008) offer a perspective that redirects the focus of discussion. They argue that much of the conversation about development has emphasized early versus late states per se, and that scientists interested in progressions would be better served by turning their attention away from characterizing beginning, end, and intermediate states (stages) and toward the *process* of developmental change. They, like Spencer and Perone, ground their work in a systems framework, although the two groups provide different kinds of illustrations. Spencer and Perone illustrate their work by running tens of thousands of computer simulations of neuronal behavior. Their figure 1 shows "real-time changes in the behavior of our neuron (or neural field) over a time scale that might encompass a day or two of experience" (Spencer & Perone, 2008, p. 1644). Adolph and Robinson illustrate their work by addressing the development of walking, a progression that follows a far more protracted path. Although the change from crawling to walking is sometimes used to illustrate qualitative change, Adolph and Robinson instead use it to argue for core continuities: Alternating leg movements are seen during the prenatal period, soon after birth in kicking, later in infancy in crawling, and still later in toddlerhood and beyond in walking. The timescale of this substantive focus is thus far more similar to the kinds of phenomena discussed by Kagan in his lead article. It would be intriguing to try to analyze the structural similarities and differences of a particular motor problem (like alternating leg movements) versus a particular cognitive problem (like a concept of number) in considering how the kinds of methods used by Adolph and Robinson might (or might not) be transferable to the illustrative domains discussed by Kagan.

Contextualizing the Challenge

Müller and Giesbrecht (2008) join Campos et al. (2008) in arguing for the importance (and legitimacy) of examining any particular behavior at any particular moment *within* (rather than isolated from) an extended developmental sequence. Furthermore, they note the value of interpreting earlier steps in view of final steps, citing Piaget's method of recurrence as a model. This approach contrasts strikingly with the second-to-second methodology of DST discussed by Spencer and Perone (2008), which is intentionally focused on the "local details of behavior." The bulk of Müller and Giesbrecht's commentary is directed to the broader epistemological differences between contemporary neonativist approaches that emphasize continuity across age (e.g., Baillargeon, Spelke, Wynn) and classic theories that identify transformations across age (e.g., Piaget, Werner, Vygotsky). They situate their discussion of programs of empirical work within the philosophical traditions of rationalism and empiricism, explain ways in which different epistemological premises lead different theories to pose fundamentally different questions and, relatedly, to use fundamentally different methods. Müller and Giesbrecht illustrate these points by contrasting nativist versus constructivist accounts of both representation and reasoning, drawing specific contrasts between the research of Baillargeon and Piaget.

At the End of the Joust

Jousts are categorized as *à plaisir* (for pleasure) or *à l'outrance* (to the death). The joust ensuing from Kagan's tossed gauntlet surely has not resulted in the death of either the continuity or the discontinuity positions. What, then, can be concluded from this collection of articles?

First—as argued in virtually any article addressing virtually any domain—the field needs more and better empirical work. Particularly important are programs of research that bring converging methods to bear on a given conclusion. This point is made emphatically and clearly by Kagan in his lead article, and it is endorsed in all five commentaries. Campos et al. (2008) provide some additional principles for how empirical work can be better; Quinn (2008) provides specific illustrations of better empirical work that can serve as a model for converging designs. Spencer and Perone (2008) as well as Adolph and Robinson (2008) discuss alternative methodologies and analytic tools for new kinds of empirical research.

Second—and again as recommended in virtually all developmental articles—the field needs more and better research on developmental process and not just on products. This point is made most explicitly in the two commentaries by Adolph and Robinson (2008) and by Spencer and Perone (2008). Observing and modeling behaviors as they unfold over time can reveal trajectories and patterns that would otherwise be invisible in the behavior itself. At the same time, though, the collection of commentaries makes it clear that recording and modeling observable incremental behaviors does not in itself resolve the problem of identifying process. That is, one can document and model behavioral differences at increasingly more microscopic levels of analysis, but this alone need not reveal causal mechanisms, at least not the kinds of causal mechanisms that may be sought. An illustration of this issue is found in Müller and Giesbrecht's (2008) discussion of the contrast between the way that Baillargeon (2008) and Piaget (1963) approach infant reasoning. They argue that Baillargeon endows the infant with nativist principles or computational devices that process encountered information. Given these devices, the infant is in essence merely a spectator. In contrast, Piaget endows the infant with the functional activity of assimilation. This assimilation (and its conjoined twin, accommodation) entails the infant's active engagement with the world, thus rendering the infant an intentional agent. But are both kinds of processes scientifically legitimate or even real? The answer to this question is, "It depends." That is, an explanatory process that is legitimate within one theory (e.g., assimilation and accommodation of Piaget) is dismissed as ephemeral by another (as when Klahr labeled these the "Batman and Robin" of developmental psychology; see Adolph & Robinson, 2008). These conflicting answers lead directly to the last point (which in essence encompasses the prior two).

The third message that may be derived from these articles is that the field needs to attend more actively to the metatheoretical context in which research is designed, conclusions are drawn, and disagreements are discussed. A failure to contextualize theories and empirical data in metatheory results in scholars misconstruing one another's meaning, or, alternatively, ignoring one another's meaning altogether. This point is developed most explicitly by Müller and Giesbrecht (2008), but it pervades the collection of articles. Constructs (e.g., concept of number, cat and dog categories) are formulated in radically different ways depending on the metatheoretical frameworks from which they emerge; likewise, the search for origins and processes differs.

As discussed in detail by Overton (2006, 2007) and Witherington (2007), theories rooted in the principles of a mechanistic – contextualist framework necessarily assert the existence of a base level of pure elements (e.g., behaviors, neurons, genes) that combine additively to produce wholes. Hence, the strategy of mechanistic – contextualist approaches is to study ever finer, directly observable units, with the goal of reaching a foundation that reveals chains of cause and effect elements. This is the mechanistic – contextualist interpretation of "process." In contrast, theories rooted in an organismic – contextualist framework eschew the assumptions of additivity of elements and the ultimate goal of identifying a bedrock foundation. Instead, their holistic perspective asserts that truly novel forms or dynamic systems emerge as the system acts upon the world. What emerges is thus different from the sum of the parts; integration yields novel systemic properties that are not characteristic of any of the parts. There is still continuity insofar as later forms subsume earlier forms, but there is also discontinuity or qualitative change.

To take a perhaps worn but still useful analogy from chemistry, the viscosity, color, and drinkability of water are emergent characteristics of water that could not be predicted from or observed within the properties of its constituent hydrogen and oxygen. Explicating the moment-by-moment processes by which electrons from hydrogen and oxygen merge in the outer rings of the molecules would still fail to explain or predict the qualities of water. Kagan's example of the movement from a perceptually based representational system to a symbolically based representational system is a more immediate developmental example. Within the mechanistic – contextualist perspective, empirical work entails the search for the bedrock appearance of the symbol at birth (or perhaps later, but still merely triggered by some biological or environmental stimulus). In the contrasting organismic–contextualist perspective, empirical work entails identifying an emergent property of a system arising from actions and integrations of earlier sensorimotor action systems. Here, symbolic representation would not be expected to be apparent in earlier forms, any more than qualities of water would be expected to be apparent in hydrogen and oxygen. Neither approach will be validated by closer observations or by converging data. Their adequacy will be assessed according to the criteria that are generally applied in the selection of any adequate scientific explanation such as the explanation's depth, coherence, and logical consistency.

In the end, then, it should be clear that the current collection of articles does—as claimed in the initial paragraph of these introductory comments—"demonstrate the diverse ways that developmental scientists conceptualize, empirically study, and draw conclusions about continuous versus qualitative change." It should be equally clear, though, that these thoughtful contributions do not converge on a single position. As long as scholars approach development from different epistemological frameworks and metatheories, there will be plurality, not consensus.

Continuity in Scholarship on Continuity

Irrespective of one's position on continuity in the study of individual development, in the everyday meaning of the word, it is incontrovertible that there is continuity in Kagan's scholarship. Over half a century ago, Kagan and Moss (1962) opened their seminal book on the Fels longitudinal study by saying: "The search for stability in physical and biological systems is a lure that attracts much scientific inquiry. The stability of that system we popularly call human behavior has long whetted the curiosity of most men, be they scientists *qua* scientists or scientists *qua* parents" (p. 1). Save for the now anachronistic use of the word *men* rather than *people*, this opening sentence could have been pulled from Kagan's current article.

And, roughly two decades after the appearance of the Fels book, but still roughly three decades ago, Kagan coedited with Brim a collection on *Constancy and Change in Human Development* (Brim & Kagan, 1980a). What made that volume so novel at the time was first, its consideration of stability and change across the entire life span, and, second, its incorporation of non-Western concepts of stability and change. The chapter by Kagan (1980) within it provided a rich discussion of how the concept of continuity has been conceptualized from a range of disciplines, eras, and philosophical positions.

Despite the long history of work on continuity by Kagan and others, key questions remain unresolved. As discussed in the commentary by Müller and Giesbrecht (2008), and as amplified in both earlier and contemporary analyses of these issues (e.g., Kagan, 1980; Overton, 2006), these questions cannot be resolved simply by better and better empirical work. In this context, it is useful to recall Brim and Kagan's (1980b) early observation: "Constancy and change are inventions of the mind, of course, a matter of subjective magnitude" (p. 2).

Given that readers will approach the articles that follow with different theories and metatheories, it is unlikely that all will derive the same conclusions about continuity and discontinuity from reading them. All will, however, come away from this collection thinking more deeply and productively about the rich conceptual and empirical work on continuity already in our books and journals, and better equipped to think more deeply and productively about the related work that will undoubtedly continue to fill our literature in the decades to come.

In Defense of Qualitative Changes in Development

Jerome Kagan
Harvard University

The balance between the preservation of early cognitive functions and serious transformations on these functions shifts across time. Piaget's writings, which favored transformations, are being replaced by writings that emphasize continuities between select cognitive functions of infants and older children. The claim that young infants possess elements present in the older child's concepts of number, physical impossibility, and object permanence is vulnerable to criticism because the inferences are based primarily on the single measure of change in looking time. It is suggested that investigators use unique constructs to describe phenomena observed in young infants that appear, on the surface, to resemble the psychological competences observed during later developmental stages.

The primary goal of scientists working in varied disciplines is to explain how a phenomenon of interest developed its observed form. A central theoretical issue in this search centers on the degree to which the current event contains some features that were present earlier and contribute to the contemporary observation. Darwin's great insight was to recognize that many of the anatomical features and functions of mammals were either absent or assumed a very different pattern in the organisms that lived millions of years earlier from which they presumably evolved. For example, the convoluted cortex of humans is not present in fish, and although the three bones of the human middle ear are derivatives of a set of bones in the fish jaw, they have a qualitatively different structure and function in the two species. Thus, it is correct to say that the bones of the fish jaw preceded the bones of the middle ear but incorrect to declare that the functions and features of the former structure contribute to human hearing.

The principle that some elements are preserved and others are transformed or lost applies to developmental stages within a species. On the one hand, the glial cells of the young embryo that guide newly created neurons to various cortical layers disappear once the mature neurons arrive at their final destination (Rakic, 1995), and the motility patterns of newly hatched birds pecking at the ground have no parallel in the motor profiles of the developing embryo (Hamburger, 1975). On the other hand, many structures and functions of the embryo's heart and mouth, once they appear, are preserved indefinitely.

The balance between transformation and preservation, which has always been a seminal node of controversy among developmental psychologists, has shifted over time as a function of new technologies, discoveries in allied disciplines, the need to replace a flawed theoretical view, and always the intellectual climate. Many social scientists had attributed the differences in academic achievement between the children of early 20th-century European immigrants to America and those of more affluent, indigenous families to the preservation of early habits and skills acquired within the family. A 1914 government pamphlet for mothers contained a warning that, although it rested on little evidence, reified the conviction that first impressions can have profound influences on the future: "The first nervous impulses which pass through the baby's eyes, ears, finger, or mouth to the tender brain make a pathway for itself; the next time another impulse travels over the same path, it deepens the impression of the first" (West, 1914, p. 59).

This belief in the preservation of the products of early experiences, which was central to behaviorism and psychoanalytic theory, thrived for over 50 years. However, the emergence of a new point of view was inevitable when the accumulated evidence failed to support strong versions of this hypothesis. Ethologists, especially Lorenz (1958) and Tinbergen (1951), who anticipated the ascent of biological mechanisms, recruited interest to the biologically prepared competences of young organisms that might be components

of later functioning. Most new scientific ideas require between 40 and 50 years before they become popular bases for inquiry. By the late 1990s, technical reports describing biologically prepared conceptual functions in young infants that shared features with those of older children began to fill journal pages (Baillargeon, 1994; Dehaene, 1997; Saxe & Carey, 2006; Spelke, 1994; Spelke & Kinzler, 2007; Wynn, 1992).

When understanding of a prolonged developmental cascade is lean, and it is difficult to imagine the intervening stages, there is a strong temptation to assume the smallest possible number of transformations between early and later phenomena in order to be loyal to the principle of parsimony. That is one reason why the 18th-century preformationists assumed that a miniature infant was present in the newly fertilized egg and why Havelock Ellis perceived a link between the look of satisfaction on the face of a nursing infant and the facial expression of lovers lost in the ecstasy of their sexual caresses (Ellis, 1900). Our fragile understanding of the degree to which the behavioral, cognitive, and emotional features of the young infant participate in more mature forms tempts theorists to assume that the early representations and functions are both necessary for, and contain some features of, those that characterize the psychology of school-aged children.

However, the habit of applying the same constructs to explain early and later performances, based on presumed similarities between the bases for early and later behaviors, does not guarantee that the initial and later forms were mediated by the same mechanism. The presence of a reliable smile to an approaching adult, which usually emerges between 3 and 5 months, reflects the fact that the infant is now able to assimilate the person's features to their schemata for the adults with whom they interact regularly. It is unlikely that this mechanism is the reason why an adolescent smiles upon greeting a close friend. Two-week-olds and 2-year-olds are likely to protrude their tongue following the same act by an adult (Meltzoff & Moore, 1977), but young infants also protrude their tongue to a slim pencil approaching their mouth because infants use their tongue to explore objects close to their faces (Jacobson, 1979; Jones, 1996; Nakagawa, Sukigara, & Benga, 2003). Hence, if the older child's behavior is called imitation, a new term should be invented to describe the apparently similar behavior of the young infant. Earlier generations of psychologists assumed that scores on the test items of the Bayley developmental scale for infants and those on the Wechsler Intelligence Scale for school-aged children represented the same psychological construct, called *intelligence*. However, the magnitudes of the correlations between the Bayley scores at 3 or 8 months and the IQ scores of older children are minimal (McCall, Eichorn, & Hogarty, 1977); hence, the infant competences should be given a different name.

The uncritical use of the same semantic term to name early and later behavioral profiles that are phenotypically distinct and that might rest on different foundations may tempt less sophisticated readers to assume that the two phenomena are exemplars of the same process. These readers should appreciate that current evidence has not yet proven with certainty that any representation, emotion, or cognitive competence present in healthy 6-month-olds is contained in the psychological functions of older children. The mind possesses a small number of stubborn biases that color the initial perception of events and the conception of the hidden structures and functions that lie beneath what is observed. One of the most profound biases, which children honor, is that "things" possess an essence that is unchanging despite surface malleability. Although young infants possess some sensory, perceptual, and motor abilities that are preserved indefinitely (e.g., the detection of sweet tastes and sounds and an automatic orienting of the eyes and head to a moving stimulus), some scholars have posited cognitive competences that go beyond these talents to include functions that are more seriously symbolic or conceptual in nature (Baillargeon, 1994; Spelke, 1994; Wynn, 1998). This claim deserves careful analysis because, if valid, it has the potential to alter our understanding of the infant and development in a radical way.

This issue assumes two major forms in contemporary research: the preservation of early emotional attachments to caretakers and the preservation of early cognitive functions. Discussion of the former has been substantial (Kagan, 1981). Hence, this article discusses only the latter issue and continues a critique initiated by others (Bogartz, Shinskey, & Schilling, 2000; Bogartz, Shinskey, & Speaker, 1997; Cashon & Cohen, 2000; Cohen & Cashon, 2006; Haith, 1998; Haith & Benson, 1998; Mandler, 2004).

The nub of the controversy centers on how much (or how little) transformation of the infant's psychological structures occurs as the child grows. If the events that transpire after 6–8 months alter early structures only quantitatively, the consequences of lawful brain growth and later experiences would seem less interesting than they would be if these changes produced qualitative transformations on the original functions. There is an important difference in meaning between (a) "The newborn's fingers closed on the object placed in its palm" and (b) "The newborn possesses a disposition for possessiveness." Many 19th-century observers cited the newborn's reflex reaction as the basis for the validity of the second statement (Fiske, 1883).

The histories of scientific controversies reveal that when two groups of sophisticated investigators disagree on the interpretation of a corpus of evidence, later inquiry usually indicates that the most fruitful explanation differs from the one promoted by either group. Early 20th-century physicists argued over whether light was a wave (the classical view) or a particle (the new quantum position). Bohr suggested that physicists should not ask what light "is" but rather how light behaves under specific experimental conditions because the experimental arrangement determines whether a wave or a particle interpretation is the most defensible. The consensus among neuroscientists working in the 1920s was that all synaptic transmission in the brain was electrical in nature. This view was challenged by a small group claiming transmission was chemical. We now appreciate that although most synapses are chemical, both mechanisms occur (Valenstein, 2005). This issue is important enough to return to it again with a different organization of facts and from a slightly different point of view.

Schemata and Semantic Forms

The psychologists who remain skeptical of the nativist claims for preservation of select early cognitive functions believe that the young infant's knowledge is contained in schemata and sensorimotor structures, whereas the older child's knowledge combines these two earlier forms with semantic networks and the ability to infer events that were not experienced. This suggestion implies a discontinuity in cognitive development because the features and organizations of the early functions differ seriously from those operative later (Cohen & Cashon, 2006; Haith & Benson, 1998; Kagan, 2002; Mandler, 2004). A schema is defined as a representation of the patterned perceptual features of an event and need not possess a semantic component or an inference as to its origin. The young infant's representation of a caretaker's face is an obvious example. The primary features of schemata for visual events are spatial extent, shape, color, contrast, motion, symmetry, angularity, circularity, and density of contour.

Eleven-year-old Mayan Indian children living in a small isolated, impoverished village in northwest Guatemala performed as well as 11-year-old Boston children when asked to recognize, following a 2-day delay, a large number of color photographs of unfamiliar objects for which they had no names, such as telescope, toaster, and golf club. Both groups of children correctly recognized the pictures close to 90% of the time (Kagan, Klein, Haith, & Morrison, 1973). It is likely that the excellent memory performance of the Mayan children was mediated by the schemata for the pictures they acquired during familiarization.

Infants, like older children, create schematic concepts or prototypes that are "averages" of repeated exposures to the same class of events. Eight-month-olds have already acquired schematic concepts for the acoustic envelopes of the vowels and consonant–vowel combinations of their language. However, they lose the ability to distinguish between phonemes that resemble the speech sounds they hear but do not occur frequently (Doupe & Kuhl, 1999). The same phenomenon occurs for schemata representing the mouth movements of speakers (Weikum et al., 2007). Infants can also create schematic concepts for temporal patterns of unfamiliar vocal sounds. Seven-month-olds first heard a 2-min speech sample containing three representations of each of 16, three-syllable utterances of the form a-b-a, but the syllables in each of the utterances were different. The only feature shared by all the utterances was that the first and third syllables were identical. After the infants were familiarized with this pattern, they heard either an utterance of the same form—a-b-a—or a new set of three syllables with a new form; for example, a-b-b. The infants were more attentive to the unfamiliar a-b-b pattern, suggesting that they had created schematic concepts for the temporal pattern of these meaningless vocal sounds (Marcus, Vijayan, Rao, & Vishton, 1999).

An important distinction between schemata and semantic structures is that only the latter imply both the essential features a referent possesses and some features it does not possess. This logic does not apply to schemata. The sentence, "The leaf is on the ground," implies that there was a time in the past when it was not on the ground; the schema of a leaf on a lawn does not contain that extra knowledge. A second distinction is that most of the time schemata can be transformed without any accompanying cognitive tension. Dreams and reveries provide classic examples. The image of a smiling face can turn into a pumpkin without any of the cognitive dissonance that would occur if a person read, "A smiling face is a pumpkin." Einstein's image of riding a light wave is said to have been one of the origins of his theory of special relativity. However, the printed sentence, "Humans can move at the speed of light" would evoke in most readers an immediate sense of impossibility.

An important difference between schemata and semantic forms involves their relations to other structures. The relations of similarity, part–whole, and contingency apply to both schemata and semantic forms, even though the specific attributes that define these relations are different for the two structures. Some relations, however, apply only to semantic structures. Only semantic forms possess the quasi-logical relations that take the form of hierarchically nested categories for objects and events (called hyponyms) and opposites for qualities (antonyms). These relations assume special prominence after 5 or 6 years of age. Most adults treat the semantic form "dog" as a logically necessary member of the semantic category "animal." Schemata do not nest into sets of hierarchical categories.

Semantic structures vary in their schematic contribution; hence, psychologists compare concrete with abstract nouns. Words like *meaning* and *truth* have far less schematic content than *girl* or *table* (Warrington & McCarthy, 1987). The different properties of semantic and schematic representations are due, in part, to the differential participation of the right and left hemispheres. The right hemisphere appears to be biologically prepared to process words with a rich schematic contribution more efficiently than it processes abstract words (Beeman & Chiarello, 1998; Deloche, Seron, Scius, & Segui, 1987; Ivry & Lebby, 1998). The meaning of the semantic term *big* depends on the specific schemata that are activated. If the child retrieved a schema for trains, big meant long. If, however, the child activated the schema for pumpkins, big meant a large area, and if the activated schema was a building, big meant tall (Sera & Smith, 1990). The semantic meaning of big varied with the schemata the child activated.

Schemata are used primarily to recognize events, places, and objects experienced in the past and often include representations of the background contexts in which events appear (Moore & Meltzoff, 2004). By contrast, semantic representations, which are often free of contextual information, are used primarily for classification, inference, comprehension of communications, and understanding causal sequences. The critical point is that schemata and semantic representations for an event award have different meanings to the predicate "know." Indeed, infants who normally treat a picture as discrepant from a familiarization set do not do so when they hear the same verbal label (a nonsense word) accompany the presentation of all stimuli during the familiarization trials (Plunkett, Hu, & Cohen, 2008). This observation implies that combining semantic information with schemata can mute the physical differences between the perceptual representations. The act of naming apples, oranges, and kiwi fruit dilutes, at least for the moment, the mind's awareness of the perceptual distinctions among these objects.

The differences between schemata and semantic forms are sufficiently salient to warrant asking whether the infant's ability to perceive the difference between arrays of two and four circles reflects the same competence that underlies the ability of 10-year-olds to learn the names for cardinal numbers and to appreciate that they form an ordinal scale of magnitude. A schema for an event, or schematic prototype for a category of event, can exist without any support from semantic elements; hence, the former are to be distinguished from semantic concepts. I would be surprised, and stare for a few seconds, if the number of books on the shelf several feet in front of my desk (and in my direct line of vision) were altered because the new display would violate my schema for that scene. However, I have no idea of the number of books on the shelf. Children watching a video of two chromosomes separating during mitosis will create a perceptual representation for the sequence without any conceptual understanding of what is happening. Young infants and many animal species can discriminate between pictures of an elm tree and an elephant and between parallel and nonparallel lines. But this evidence does not mean that they possess the semantic concepts plant, animal, or parallel.

It is also the case that individuals can have some semantic understanding of a phenomenon without a corresponding set of schematic representations. I know that if I were bitten by an Anopheles mosquito infected with malarial parasites I would come down with a fever, even though I have no schemata for the parasite or the toxins it produces in my body. The extensive literature showing that infants under 8 months display increased attentiveness to events that violate a perceptual expectation does not require positing any semantic representation implying an understanding of the event's origins or consequences. This suggestion does not mean that young infants do not possess semantically based conceptual representations, only that this hypothesis is not yet proven beyond reasonable doubt (Aslin, 2000).

The Source of Evidence

The meaning and validity of every scientific conclusion based on empirical data always rest on its source of evidence. This principle is one of the most important dividends of the 20th-century advances in physics that culminated in quantum mechanics. The statement that turtles and crocodiles are phylogenetically distant is true if similarity in their skeletons is the source of information but false if similarity in DNA strings is the evidence.

This principle is relevant to the concerns of this article because the evidence for most claims about infants' conceptual capacities is total time attending to particular events rather than other indexes of attention, such as duration of the first fixation, the longest fixation, the number of times the infant looks away from the stimulus, and the number of shifts of attention between a pair of events. Aslin (2007) notes that these variables might reflect different cognitive processes, a position articulated by Lewis (1967) over 40 years ago. This possibility is supported by the fact that infants younger than 1 year who displayed frequent attention shifts between a pair of stimuli, together with shorter individual fixations, showed larger increases in attention to a novel event than others (Frick & Colombo, 1996; Rose, Feldman, & Jankowski, 2003). In addition, the number of shifts between a pair of stimuli distinguished between drawings with different element densities better than total fixation time (Tan & Bryant, 2000) and the mean and the longest fixation time often invite different conclusions (Courage, Reynolds, & Richards, 2006).

In addition, most investigators probing infants' concepts do not quantify brain profiles, autonomic reactions, conditioned operants, facial expressions, crying, vocalizing, or smiling as possible indexes of the state provoked by violation of an expectation. The essential premise in the design of most experiments is that unexpected events recruit longer bouts of attention than those that are expected. These investigators assume implicitly that events that do not match an acquired perceptual representation create a state that neuroscientists believe is accompanied by activation of the parahippocampal region, amygdala, and parietal lobe and, as a consequence, a prolonged orientation (Joseph et al., 2006). However, I will orient and stare out the window of my study for several seconds if I hear an unexpected outside sound and will gaze at the faucet in my kitchen if no water flows when I turn it, without any understanding of the origin of the sound or the reason for the failure of water to flow. A prolonged orientation to an unexpected event is not synonymous with knowing or inferring, anything about its origins or conceptual category (Saffran, 2001). Rather, looking reflects a temporary state of uncertainty. That is why 6- and 9-month-olds look at their mother when an unexpected event occurs (Walden, Kim, McCoy, & Karrass, 2007).

Moreover, failure to show a longer bout of attention to one event compared with another does not mean that the infant did not detect the distinctive features of the two events or did not experience an expectancy violation. Infants familiarized on a circle enclosing two dark, horizontally placed circles in the upper part of the design showed increased looking if the horizontally placed circles were vertical but did not show prolonged looking if the circles were replaced with squares, even though infants can detect the difference between squares and circles (Kagan, Linn, Mount, & Reznick, 1979). Thus, failure to show increased attention and the display of increased attention are ambiguous and do not demand only one interpretation.

A Trio of Influences on Looking

Many investigators ignore three factors that can influence duration of attention to an event: (a) the possibility that the relation between unfamiliarity and duration of looking is curvilinear rather than linear, (b) the influence of brain maturation (i.e., uniform changes in all healthy infants in brain structure and physiology over time), and (c) the significance of the physical features of the stimuli.

Linear or Curvilinear Functions

Although the developmental scientists who rely on total duration of attention never say so explicitly, they assume implicitly that the relation between expectation and looking time is linear. The less expected an event (and, by inference, the more discrepant it is from the infant's schemata), the longer the bout of attention devoted to it. Although familiarity and expectedness are not synonyms, it is reasonable to argue that infants and adults have a higher expectation of seeing a familiar than a less familiar event (Cycowicz & Friedman, 2007).

One problem with the assumption that unexpected events always recruit more prolonged attention than expected ones is that the infants' behaviors do not always conform to that prediction. For example, 4-month-old infants who saw a photo of their mother alongside a photo of an unfamiliar woman looked longer at the more familiar parent. They also looked longer at pictures of faces that had the familiar, ecologically valid arrangement of facial features than at faces with the features rearranged, even though the latter were less familiar and therefore less expected. By contrast, 1-year-olds devoted longer bouts of attention to a rearranged face than to a familiar face because their schemata for faces had become much firmer and, as a result, the rearranged faces were now optimally discrepant (Kagan, 2002). Seven-month-old infants looked longer at the vocal source of short sentences containing words they had been familiarized with a day earlier than at the source of spoken sentences containing totally unfamiliar words (Houston & Jusczyk, 2003), and looked longer at a face whose perceptual form matched a vocalization than at a face paired with a discordant vocal sound (Soken & Pick, 1999). These data suggest that the relation between expectation and duration of attention is often curvilinear, rather than linear, when the event is simple, not part of a complex sequence, and there is a minimal burden on the infant's working memory.

Even newborn infants honor this principle. Samples of newborns were familiarized with the nonsense word *titi* played from one of the two speakers placed on either side of the infant's head. The newborns turned their head to the initial presentation of the word. After habituation, the infants heard either the same word or one of the four variations created by altering the fundamental frequency of the original sound by 7%, 14%, 21%, or 28%. The infants were most likely to orient to a stimulus that altered the fundamental frequency by 14% or 21% (moderate discrepancies) and less likely to orient to the more extreme alteration (Weiss, Zelazo, & Swain, 1988; see also Fenwick & Morrongiello, 1998; Saffran, Loman, & Robertson, 2000). Three-week-olds looked longer at 2 × 2 checkerboards than at 8 × 8 and 24 × 24 designs; 8-week-olds looked longest at 8 × 8 checkerboards; and 14-week-olds stared longest at the 24 × 24 forms (Brennan, Ames, & Moore, 1966).

The curvilinear relation between duration of attention and discrepancy is found in older infants. Seven-month-olds were first familiarized with either a sphere or a cylinder. When infants struck a bright yellow padded lever, they were allowed a 2.5-s view of either a sphere or a cylinder. After the infants had habituated and stopped striking the lever, they saw one of the four stimuli. The infants who had been familiarized on the sphere saw a pear-shaped object, club, cylinder, or irregularly shaped styrofoam object. The infants who had been familiarized on the cylinder saw the club, pear-shaped object, sphere, or styrofoam object. The profiles of attention revealed a curvilinear relation between degree of discrepancy from the acquired schema and duration of attention. Infants who had been familiarized on the sphere showed their longest bout of attention to the club, which was moderately discrepant from the sphere; the infants who had habituated on the cylinder showed their longest bout of attention to the sphere. Few infants showed their longest bout of attention to the styrofoam object, even though it was maximally discrepant and, therefore, minimally expected (Hopkins, Zelazo, Jacobson, & Kagan, 1976; see Saffran & Thiessen, 2003 for affirmation of this idea with multisyllable utterances).

McCall and McGee (1976), who examined many studies on the relation between discrepancy and attention, concluded, "There are at least seventeen separate samples of infants that displayed the inverted U-discrepancy function. Seventeen exemplars of one specific quadratic curve would appear to make the discrepancy hypothesis plausible and worthy of further examination" (p. 13).

Maturation

The term *maturation* refers to a uniform progression of changes in brain organization and function in infants growing in any reasonably natural environment. Some of these changes are detailed in a later section. The point to be made here is that the maturational changes that occur between 2 and 3 months affect the relation between looking time and familiarity because infants 4 months or older are more likely than younger infants to relate an event to an established schema. Two-, 4-, and 6-month-old infants sat across from an unfamiliar woman who either interacted with the infant as a parent would or sat with an immobile face displaying a neutral, happy, or sad expression. Because the less mature 2-month-olds did not relate either event to their acquired schemata they looked equally long at both events. The 4-month-olds, who did relate the events to their schemata, devoted longer attention to the stranger when she was behaving like a parent because this posture was moderately discrepant from their past experience; whereas, the immobile posture was too novel and an attempt at assimilation was inhibited (Rochat, Striano, & Blatt, 2002). Two-month-olds are also too immature to perceive an object partially hidden by an occluder as a unitary entity (Johnson et al., 2003) and behave as if they do not expect an object in midair, with no visible support, to fall to a surface (Sitskoorn & Smitsman, 1995). Children will revise that belief when they learn later about astronauts taking space walks.

The maturational changes that occur between 6 and 10 months are accompanied by the introduction of a new process governing attention. Kagan, Kearsley, and Zelazo (1978) demonstrated, over 25 years ago, that holding the stimuli constant, there was a U-shaped function between age and duration of attention across the interval from 4 to 12 months, with a nadir between 6 and 9 months, followed by increased attention to the same events for the rest of the 1st year. Courage et al. (2006) replicated this result with eight different categories of visual stimuli. Other evidence suggests that the enhanced ability to hold a schema for a past event in a working memory circuit and to relate a present event to that schema and to representations acquired in the past are critical additions to the infant's talents at this time (Diamond, 1990; Kagan & Herschkowitz, 2005). As a result, infants older than 8 or 9 months are likely to create a perceptual prototype for frequently experienced events and to ignore discrepancies in single features that do not alter the holistic, gestalt quality of the schema. By contrast, infants less than 8 months often treat discrepancies in single features more seriously (Doupe & Kuhl, 1999; see also Weikum et al., 2007).

The Role of the Stimulus

Many experiments are insufficiently attentive to the physical features of the stimuli presented to infants because they are not of primary interest to the scientist. Ross and Dannemiller (1999) note that motion, color contrast, and luminance compete for the young infant's attention because the brain always reacts to the physical features of an event independent of its meaning. For example, removing or muting the contrast between the color of the background and the color of the target stimulus can affect looking behavior in a significant way. Arrays containing stimuli with red features usually recruit more attention than those with green or blue features, but investigators often ignore this fact when they select the stimuli for their experiments (see e.g., Shimizu & Johnson, 2004). Adults viewing curved or angular versions of neutral objects showed greater blood flow (implying activation) to the amygdala, superior temporal gyrus, anterior cingulate, and select visual areas to the angular compared with the curved forms (Bar & Neta, 2007). Thus, infants might look longer at a toy block than at a hand after seeing a beanbag move spontaneously (without obvious provocation) because the block contained more linear, angular features than the hand and, therefore, might have activated brain sites that provoke a prolonged bout of attention. (See Saxe, Tzelnic, & Carey, 2007, who did not acknowledge this possibility.)

The Concept of Number

I now consider in more detail the evidence behind three classes of claims that do not differentiate between schematic and semantic representations, fail to acknowledge the importance of the source of evidence, or are indifferent to the physical features of the stimulus arrays. The three claims refer to young infants' possession of the concept of number, physical impossibility, and permanent objects. The concept of number is considered first. Some scientists attribute to young infants a concept of number, as contrasted with a perceptual representation of quantity because they can distinguish between displays of different numbers of dark circles in a habituation – dishabituation design. However, Fantz and Fagan (1975) noted, over 30 years ago, that young infants look longer at a design with 20 squares than at one containing only 4 squares because of differences in the amount of contour derived from a combination of the size of each element and the number of elements.

Mix, Huttenlocher, and Levine (2002), who reviewed the literature on the concept of number, concluded that the infant's ability to discriminate among different numbers of elements, as long as the numbers were less than four or five, was based primarily on perceptual features, especially total area, size, and density of the elements, and total contour length (see Tan & Bryant, 2000, for a similar conclusion). When these physical properties were controlled, 6-month-olds behaved as if they could not discriminate between one and two objects (Xu, Spelke, & Goddard, 2005). These observations imply that the infant's ability to perceive differences in the size and density of elements and amount of contour is qualitatively different from the older child's symbolic concept of number (see Feigenson, Carey, & Spelke, 2002). Indeed, in some contexts, 12-month-olds behave as if they can only create and hold in working memory perceptual representations for up to three objects (see Ross-Sheehy, Oakes, & Luck, 2003). One-year-olds who see an examiner place four crackers in a box do not persevere in searching for additional crackers after retrieving the first one, but will do so if they see the examiner place only two crackers in the box, implying that they regard any quantity of cracker greater than three as belonging to a single, amorphous category (Feigenson & Carey, 2005). Le Corre and Carey (2007) suggest that the representation of the cardinal numbers that children use when they count is not an obvious derivative of the infants' perceptual representations of quantity.

My front lawn has eight trees, a fact I was unaware of until moments ago when I counted them. But when I gaze out the window in summer, I do not see a set of eight objects, but an array of tall green-gray objects in the context of a sloping, green lawn. Major changes occur between the infant's perceptual ability to discriminate between arrays of three and six circles and a 10-year-old knowing that an array of three circles can, if one wished, be named with the semantic concept "3," which is symbolic of a magnitude less than the concept "4." Infants and adults would probably perceive a pile of playing cards composed of two full decks similarly, but only the adults know that they can conceptualize this event as one pile, two decks, or 104 cards.

Number is not an inherent property of a visual experience but one that is imposed on an event. An infant who discriminated between a cup three-fourths full of liquid and one one-fourth full does not possess the mathematical concept of fractions. Attributing number concepts to infants simply because they can discriminate among arrays containing different numbers of elements is analogous to attributing a number competence to pigeons who can be taught to peck at a key exactly four times (Machado & Rodrigues, 2007), to the sensory cells of the basilar membrane because they respond differently to varied sound frequencies, and to honeybees, whose behavior upon returning to the hive is affected by the distance between the hive and a flower bed.

If the claim that infants possess a concept of number, as contrasted with schemata for varied arrays of elements, is suspect the suggestion that young infants can "add" numbers must also be vulnerable to criticism. Wynn (1992, 1998) has written that young infants possess a mental mechanism devoted especially to number and can "add numerical quantities." The evidence for this bold declaration is that young infants looked longer at a stage containing one doll than at one with two dolls after seeing a sequence in which a human hand placed a second doll on a recently curtained stage that had contained one doll. But Wynn presented the infants with only two test events—either one or two dolls—and did not allow them a choice between one, two, or no dolls. Infants pay little attention to a stage containing no dolls, even though this is an unexpected events for infants who were administered the addition procedure (Cohen & Marks, 2002). This observation should raise some doubt regarding the claim that infants can add numbers. (See Bogartz et al., 1997, for another example of the importance of presenting more than two test events.) It is also relevant that the profile of attention shown by 5-month-old boys administered a partial replication of Wynn's procedure did not support her conclusion (Moore & Cocás, 2006).

More important, if infants were able to add numbers it should make no difference if they first saw an object on a stage and then saw a second object added behind a screen (Wynn's procedure) or initially saw no object on the stage but watched two objects being added sequentially to a stage located behind a screen. However, 8-month-olds exposed to this procedure did not behave as if they could add 1 + 1 (Uller, Carey, Huntley-Fenner, & Klatt, 1999). Furthermore, 3-year-olds behave as if they do not "know" an essential feature of the concept of number; namely, that the number of objects in an array remains the same despite a change in their spatial arrangement (Halford & Boyle, 1985). If preschool children do not possess this essential property of number, one can question the conclusion that the infants' representations of dolls moving on and off a stage share important features with the concept of number held by school-aged children. Notice that Wynn could have written that infants are able "to combine schemata for two visual events and hold the combined representation in a short term memory circuit." This conclusion would be less vulnerable to criticism, though still requiring proof, but it would not have made the headlines of our major newspapers. The predicate "add" has a specific meaning in mathematics and psychologists cannot treat that definition permissively. Differentiate and integrate have specific meanings in the calculus that are not the meanings understood by social psychologists.

It also remains a possibility that other processes operative in Wynn's procedure can explain the data. One such process involves the curvilinear discrepancy principle. The last event the infants saw in the procedure for addition was a single doll located at the edge of a curtained stage. The test event contained either two dolls or one doll in the middle of a stage with no curtain. One can argue that a single doll in the middle of a stage with no curtain is moderately discrepant from the last event the infant saw, whereas two dolls are more discrepant. Hence, looking at one doll would be predicted by the curvilinear principle.

Second, young infants often look at the more familiar event after seeing a sequence of new experiences. In the procedure for addition, three distinct events occurred before the test trial and on two of those occasions, the infants saw one doll and never saw two dolls. Thus, they might have looked longer at one rather than two dolls on the test trial because it was the more familiar event and not because they expected to see two dolls.

Furthermore, Cohen and Marks (2002) remind us that young infants usually look longer at the most recent, rather than at the more remote, event when exposed to a sequence of events the investigator assumes is perceived as connected because the young infants forgot the initial experience. Six to 7-month-olds first watched two different objects placed sequentially behind separate occluders on distinct places on a stage. Although they showed increased attention when the object that had been hidden last changed shape and color, they failed to do so when the object placed first behind the occluder underwent the same change (Kaldy & Leslie, 2005). The authors argued that infants less than 9 months, before the maturational transition associated with an enhancement of working memory, have difficulty retrieving the initial events of a sequence. The last event Wynn's infants saw in the addition procedure was a single doll. A similar interpretation can be applied to a later study with 9-month-olds watching films of five geometric forms moving or emerging from behind an occluder (McCrink & Wynn, 2004).

The young infant's ability to retain schemata for events experienced many seconds earlier and to retrieve them in the service of processing a new event, grows linearly during the 1st year (Fox, Kagan, & Weiskopf, 1979; Pelphrey et al., 2004; Ross-Sheehy et al., 2003). Most infants under 7 months have difficulty remembering the location of an object when there is only a 7- to 10-s delay between the hiding of the object and the time when the infant is allowed to reach for it because the connectivity of medial temporal lobe structures and prefrontal cortex is immature (Diamond, 1990). Infants younger than 8 months looking at pairs of faces consisting of one unchanging photo and a series of different unfamiliar faces required more than 60 s of exposure to the unchanging face before they looked consistently longer at the novel stimulus (Rose, Feldman, & Jankowski, 2002; see also Rose, Feldman, & Jankowski, 2001). Children less than 3 years old typically do not integrate relevant past experiences with their understanding of the present moment (Povinelli, Landry, Theall, Clark, & Castille, 1999).

In light of this evidence, it is surprising that Dehaene (2007) writes that psychological phenomena cannot be understood fully until they "have been related to all levels of brain organization" (p. 29) and contends that infants possess a concept of number localized in the intraparietal region of the brain. I assume Dehaene means that there should be a close correspondence between the behavioral and the biological evidence. If Dehaene is correct, the hypothesis localizing number in the intraparietal region of the infant's brain is suspect. First, the biological changes that occur in this region and in its connections after the 1st year could alter its functions. Second, native adult Chinese and English speakers show different patterns of brain activity while solving addition problems (Tang et al., 2006). Third, adults required to select the most likely answer (from two alternatives) to a series of multiplication problems showed the largest increase in blood flow in precentral and inferior gyri and displayed a decrease in blood flow to the intraparietal area (Ischebeck, Zamarian, Egger, Schocke, & Delazer, 2007). Fourth, a major function of the intraparietal area involves the perception of a spatial array of objects, mediated primarily by the right hemisphere (de Schonen & Mathivet, 1990; Hagler, Riecke, & Sereno, 2007). The fact that the intraparietal area is active when humans see a display of four circles is more properly described as a response to a spatially distributed array of discrete stimuli rather than a reaction to the recognition that there are four objects. Blood flow profiles to the intraparietal area were different to spatially distinct arrays of three objects (one array grouped two of the objects and the other did not; Xu & Chun, 2007). If this cortical area "counted" the number of objects, the blood flow patterns should have been similar to both arrays because they contained the same number. Furthermore, the cortical areas activated when adults were looking at arrays with varied numbers of objects were different from the areas active when they were reading numbers (Roux, Lubrano, Lauwers-Cances, Giussani, & Demonet, 2008). These facts, and others, are inconsistent with the hypothesis that the infant's behavior to visual displays varying in number of elements reflects a competence that is similar to the older child's concept of number when doing arithmetic calculations.

Inferring Physical Impossibility

The claim that infants "know" that solid objects cannot pass through a solid barrier has also generated strident debate and readers are referred to volume 1 of the journal *Infancy* for a set of important articles, both pro and con, on this issue (Aslin, 2000). Baillargeon (1994) believes that infants less than 8 months old know that one solid object cannot pass through another. In one experiment, 6.5-month-olds watched a screen move in a 180-degree arc on a stage, resembling the motion of a drawbridge. The examiner then placed a solid box behind the screen to inform the infant that the screen could no longer traverse the full 180 degrees because the box would obstruct its passage. On the test trial, some infants saw the screen traverse 157 degrees, an impossible event; others saw the screen move in an arc of 112 degrees, which is a possible event. The infants looked longer at the impossible event. But the last dynamic event the infant saw was the screen moving in an arc of 180 degrees; therefore, seeing it move 157 degrees was more similar to that event than the 111 degree motion and, in addition, involved more motion (Baillargeon, 1994). Infants who saw a screen move 112 or 180 degrees in a setting where both were possible events looked longer at the event with more motion, that is, the 180 degree movement (Rivera, Wakely, & Langer, 1999). Baillargeon suggested, however, that her evidence does not mean that infants respond to physical events "in terms of abstract underlying principles, but in terms of concrete categories corresponding to specific ways in which objects behave or interact" (p. 139). I interpret "concrete categories" to mean perceptually based schemata rather than semantically based conceptual representations of physical impossibility.

Schilling (2000) recognized that 4-month-olds might require a great deal of experience to create a firm schema for the complicated scene of a moving screen and an obstructing object on a stage. Hence, he gave one group of infants 7 exposures to the screen moving the full 180 degrees and gave another group 12 exposures to the same sequence. Schilling then placed an obstructing object on the stage (but one less salient than the brightly colored block used by Baillargeon, 1994) and had the screen rotate either 180 degrees or 112 degrees. The infants who had only seven exposures and therefore may not have habituated to the sequence, looked longer when the screen moved a full 180 degrees, the impossible event. However, the infants who had seen the 180 degree movement 12 times, and therefore were more likely to be bored, looked longer when the screen moved 112 degrees, the possible event that was discrepant from their more firmly formed schemata for the full 180 degree traverse. (See Baillargeon, 2000, for a rebuttal to Schilling, 2000.)

Schoner and Thelen (2006) have also questioned Baillargeon's (1994) conclusion that differential looking is a sufficient basis for assuming that infants know one object cannot pass through another. These scientists prefer the concepts of activation and inhibition fields, which vary continuously in strength and compete with each other. Schoner and Thelen assume that infants are prompted to look at a stimulus when the strength of the activation field motivating attention is stronger than the inhibition field motivating looking away. However, they agree with this author and others that the physical features of the stimulus and the timing and order of stimulus presentations can influence, in a serious way, the profiles of fixation time. These investigators have formalized the activation and inhibitory processes in a neural model that explains the evidence without reference to objects or physical impossibility.

In a second procedure designed to evaluate the infants' appreciation of physical impossibility, 7.5-month-olds were familiarized on one of two displays of a ramp, a track, and an agent object that could contact a target object. The infants in the potential contact group saw the agent and target separated by a half barrier; hence, the former theoretically could contact the latter. The infants in the "no-contact" group saw a full barrier between the ramp and the track; hence, the agent could not contact the target. The test display, which was similar for both groups, presented infants with the top half of the barrier but the bottom half covered with a curtain, making it appear as if there were a full barrier between ramp and track. The agent rolled down the ramp, passed behind the curtain, and seconds later the target moved on the track. Because the no-contact group looked longer at this event than the contact group, the authors concluded that these infants "knew" the agent could not strike the target and cause it to move (Kotovsky & Baillargeon, 2000). However, the test event was moderately discrepant from the familiarization experience for the no-contact infants because a curtain replaced the bottom half of the full barrier. The test stimulus was a more serious discrepancy for the "contact" group who had seen only a half-barrier during familiarization and no curtain. Thus, the curvilinear principle could account for these data.

It is also relevant that 6-month-olds did not show prolonged attention to a physically impossible movement sequence involving an agent and target object, and 10-month-olds, who saw both a possible and an impossible sequence without any prior familiarization, did not look longer at the physically impossible event (Oakes & Cohen, 1990). Moreover, 10-month-olds first familiarized on an impossible sequence behaved as if discrepancy was the primary determinant of attention for they looked longer at a possible sequence than at an impossible one (see Oakes, 1994, for a similar result).

Saxe and Carey (2006), who reviewed the research on the infant's ability to infer a necessary causal relation when an agent object contacts and dislocates a target object, concluded that infants become attentive when there is a violation of a perceptually based expectation of a target's movements, but they are not very attentive when the target changes color or state, suggesting that the target's motion has perceptual salience. Saxe and Carey suggested that perception of a "causal" relation between two events is not present at birth and, like the perception of the unity of an object, requires postnatal experiences. By the second half of the 1st year, infants have had a great deal of experience seeing hands throw or move objects and these experiences create schemata for hands as the origins of motion in another object. Hence, they look longer when a human hand is the agent that changes the object or location it approaches on a stage than when the agent is an oval green object (Shimizu & Johnson, 2004). Infants can learn perceptual expectations with surprising speed (Kochukhova & Gredeback, 2007). However, the important point is that the young infant's schematic representation of a sequence of physically plausible events is not a general competence but one that is limited to the classes of events that infants have encountered in the past. That is why the patterns of looking in 4-month-olds watching an object move in horizontal or diagonal trajectories, which included passing behind an occluder in a continuous or discontinuous trajectory, failed to support the hypothesis that young infants possess an understanding of the possible or impossible motions of objects (Bremner et al., 2007).

The expectation that an object will move when struck by another does not mean that infants understand why a movement did or did not occur (Schlottmann, 1999). Haith and Benson (1998) point out that when a moving object does not contact a target object and, following a brief delay, the latter moves (an impossible sequence), infants might be reacting to the difference in timing between the familiarization experience, in which there was simultaneity between the contact of agent with target and the subsequent motion of the target and the test event in which simultaneity was missing. Most 4-year-olds are unable to report the reasons why an impossible event cannot occur (Shtulman & Carey, 2007). Older children have learned that morning light always follows the dark of night and would be surprised if there were no light when they woke at 8 a.m., but they do not believe that the latter was the cause of the former.

Preschool children who have seen restaurant scenarios on television are likely to have a perceptual schema for a sequence in which an adult writes down on paper what sitting adults say and, minutes later, delivers some food to the latter. Hence, they would be surprised if the waiter brought the customer a toy car. But that fact does not mean that the child "knows" anything about the chain of events that transpired between the perception of the adult writing on a pad and the later delivery of the food. Many adults have a perceptual schema for hitting the button on their computer and seeing, seconds later, the word *Welcome* on the screen. But they do not possess a conceptual representation of the causal sequences that occurred between the two events. Rats can acquire an expectation of receiving food when they strike a lever and might show behavioral signs of surprise if the food did not appear, but few scientists would claim that the animals possessed a representation of the causal relation between their actions and the delivery of a few pellets. There is a great deal of evidence to suggest that the first signs of the ability to infer the invisible events that might mediate an outcome do not emerge until the middle of the 2nd year (Kagan, 1981). Causality, as Hume understood, is a symbolic invention and is not contained in a perceptual schema.

It is important to appreciate that 2-year-olds, who have some language and an improved working memory, do not infer the correct location of a ball that rolls down an incline to strike a tall, clearly visible occluder. In this study, the examiner placed the occluder behind one of the four doors over a series of trials and asked the child to guess which door should be opened in order to retrieve the ball. Two-year-olds could not solve this problem; that is, they were unable to infer the correct door to open from their perception of the location of the occluder (Berthier, De Bois, Poirier, Novak, & Clifton, 2000). However, 2-year-olds do show increased attention if a puppet, who had been successfully retrieving a ball from the correct door, failed to reach for the object at the door representing the correct location (Mash, Novak, Berthier, & Keen, 2006). Hood, Cole-Davies, and Dias (2003) performed a similar experiment with a similar result. Two-and-a-half-year-olds stared for several seconds when a toy that had rolled down a ramp and struck an occluder suddenly appeared on the other side of the occluder—a physically impossible event—but failed to search correctly for the toy at the place where the occluder rested.

These results affirm the earlier suggestion that the predicate "know" has two different meanings in these varied experimental contexts. One refers to prolonged attention following the violation of a perceptual expectation; the second refers to a conceptually richer representation that includes an inference representing a necessary relation between the location of an occluder and the location of an object. Because the 2-year-olds did not reach correctly for the object when they could see where the occluder rested, investigators may be going beyond the evidence when they conclude that infants less than 1 year "know" that objects cannot pass through a solid barrier and imply that "know" has the same meaning for infants that it has for older children.

Object Permanence

Eight-month-olds administered the Piagetian A not B task often stare briefly at the correct location of a hidden object but reach incorrectly (Ahmed &

Ruffman, 1998; Hofstadter & Reznick, 1996). Some psychologists have used the staring response as evidence that infants "know" the correct location of the object. But neuroscientists have learned that the dorsal circuit, which influences the frontal eye fields in the left hemisphere and mediates the location of an event (the "where" circuit), matures earlier than the ventral circuit that mediates the representation of an object-qua-object (the "what" circuit; Campana, Cowey, Casco, Oudsen, & Walsh, 2007; Rao, Zhou, Zhou, Fan, & Chen, 2003). Knowing the location where an event just occurred is not equivalent to knowing that a particular object, seen hidden seconds earlier, is resting in that location. I will orient in the direction of a fast-moving object detected in my peripheral vision without having any knowledge of the features or category of the object. Hence, looking at the correct location where a toy had been hidden may not represent a point on a continuum of object permanence but rather a totally different cognitive process (Ruffman, Slade, Carlos-Sandino, & Fletcher, 2005). Some dog breeds will run hundreds of yards to retrieve a stick thrown by their owner even though they cannot see the object they are racing to retrieve. It is not obvious that the dog knows that the stick is a permanent object that cannot disappear.

In summary, the increased fixation time observed after violation of a perceptual expectancy is influenced by at least six different factors, depending on experimental conditions: (a) the event seen last in a sequence and the timing of the events in the sequence, (b) the more familiar event in a complex sequence, (c) the more unfamiliar of two test events, (d) an unexpected event, (e) the moderately discrepant event when more than two unfamiliar events are presented, and always (f) the salient physical features of the event. No investigation, to my knowledge, has adequately controlled for all six factors. Hence, it is reasonable to question the claim that 4-month-olds have a concept of number, can add, and "know" why an object cannot pass through a solid substance. The same skepticism applies to the claim that infants know that an illustration of a cube, resembling an Escher drawing, is physically impossible to construct. Careful examination of the details in the possible and impossible cubes reveals subtle differences in their physical features (Shuwari, Albert, & Johnson, 2007).

Including Other Measures

Because all conclusions are constrained by their source of evidence, it is relevant that measures other than total fixation time, including operant responding and changes in heart rate, skin conductance, and vagal tone, occasionally invite different inferences about an infant's knowledge (Bornstein & Suess, 2000; Shields & Rovee-Collier, 1992). The various waveforms in the event-related potential (ERP) also lead to different conclusions regarding the state of an infant following violation of an expectation. For example, 6-month-olds who saw, in a random series, a familiar and unfamiliar face, and a familiar and unfamiliar object showed a larger negative waveform at about 400 ms (called Nc) to the familiar events, but a larger positive slow waveform at about 800 ms to the unfamiliar stimuli (de Haan & Nelson, 1999).

Infants between 4.5 and 7.5 months were first familiarized on two geometric forms (A and B) and later saw form A on 60% of the trials, form B on 20% of the trials, and a third novel form (C) on 20% of the trials. The Nc waveform was largest to the novel form C. But had attention been coded in the usual fashion many infants would have looked longest at form B, the moderately discrepant event (Reynolds & Richards, 2005). Infants familiarized on trios of objects that varied in shape, color, and orientation over trials failed to show an increase in attention to the unexpected appearance of two objects but did display a clear change in an ERP waveform to two objects (Arriaga, 2001). Finally, there was no correlation in 7-month-olds between the difference in fixation time to faces displaying a fearful compared with a happy expression (larger values to the fear face) and the differences in the magnitudes of the Nc or P400 waveforms to these two facial expressions, despite larger values to the fear face (Leppanen, Moulson, Vogel-Farley, & Nelson, 2007; see de Haan & Nelson, 1997; Slater, Morison, & Somers, 1988; Webb, Long, & Nelson, 2005, for additional support of the claim that different conclusions follow from data on looking time compared with ERP evidence).

Vocalization, smiling, and changes in facial expression can also reflect psychological states provoked by violations of expectations that looking times fail to reveal. For example, infants looked longer at a speaker baffle playing the babbling of an unfamiliar infant than at one playing their own babbling, but the infants vocalized more to the latter event, even though they did not usually hear tape recordings of infant babbling and, therefore, both events were unexpected. Four-month-olds playing peek-a-boo with an adult who suddenly displayed a sad, rather than a smiling, face showed no change in fixation time but displayed a change in facial expression (Montague & Walker-Andrews, 2001). On occasion, smiling reflects recognition of a discrepant event when fixation time does not. Three-month-olds showed equivalent fixation times to pictures of a normal face and a face with a single cyclopean eye in the middle of the forehead but only smiled to the regular face (Lewis, 1967).

Prolonged attention to an event appears to reflect the state created by an event that engages a schema but is not assimilated immediately. Babbling or smiling reflects the state created by a discrepant event that is easier to match to a schema and is assimilated more rapidly (Kagan et al., 1978). Moreover, the combination of fixation time and smiling, coded simultaneously, was the best predictor of how many exposures to a familiarization stimulus were required before 5- to 9-month-old infants looked reliably longer at the novel member of a pair of events (Rose, Futterweit, & Jankowski, 1999).

An elegant experiment with monkeys revealed the inferential error that is possible when investigators use only one measure to evaluate a cognitive process or structure. Four rhesus monkeys were trained over many days to make a simple motor response whenever a particular human face appeared on a screen. After the animals had learned to discriminate this face from many others, the psychologists altered the features of this target face in order to discover the essential features of the monkeys' schema for the familiar face. As expected, the animals were less likely to make the motor response (indicating recognition) when the size or location of the eyes was altered than when there were alterations in the nose or chin, suggesting that the size and placement of the eyes were the most essential features of the monkeys' schema for the target face. But, surprisingly, some animals showed no change in behavior to a face with no eyes at all and behaved as if this stimulus were the target face (Keating & Keating, 1993).

This unexpected result invites one reasonable and one unreasonable explanation. The latter implies that monkeys perceive faces in a manner that is qualitatively different from humans; no child would treat a face with no eyes as equivalent to one with eyes. If this explanation were correct, a great deal of theory would have to be rewritten. Hence, the more reasonable interpretation is that the monkey's behavior is ambiguous in meaning and can be evoked by more than one psychological state. I suspect this is the proper inference and, therefore, urge more caution among scientists who make claims about what infants know that are based on only one measure, whether that measure is fixation time, instrumental kicking, ERPs, autonomic response, smiling, or babbling. There is, at present, no behavioral or biological reaction that is restricted to a single set of conditions and demands only one inference. Readers are reminded of the earlier commitment by behaviorists to the concept of the strength of a habit. However, this a priori concept lost its attractiveness when research revealed that the three measures of habit strength in a hungry rat—speed of running down an ally to a goal box, making the correct turn in a maze, and amount of food consumed after arriving at the goal—were not highly correlated.

Influence of Brain Maturation

The lawful alterations in brain structure, chemistry, and physiology over the first decade raise the possibility of qualitative changes in the psychological structures that represent objects, number, or causality in infants compared with older children (Lenroot & Giedd, 2007). If the brains of 6-month-olds were essentially similar to those of 16-year-olds, the nativist argument would be more attractive, but this is not the case (Almli, Rivkin, McKinstry, & the Brain Development Cooperative Group, 2007). For example, during the second half of the 1st year, there is a major spurt of differentiation in both pyramidal and inhibitory interneurons in the prefrontal cortex, a broader distribution of the double bouquet interneurons in Layer 3, an increase in the number of spines and extra large excrescences on the proximal dendrites of pyramidal cells in the CA3 region of Ammon's horn of the hippocampus, and increased glucose uptake in the lateral, frontal, and dorsolateral prefrontal cortex (Chugani, 1994; Huttenlocher, 1974, 1990; Kostovic, 1987, 1990; Mrzljak, Uylings, Van Eden, & Judas, 1990). Furthermore, the connections between the amygdala–temporal lobe and the prefrontal cortex are strengthened during the second half of the 1st year, in part because axons within the capsula interna develop myelin (Brody, Kinney, Kloman, & Gillis, 1987; Chrousos & Gold, 1992). It cannot be a coincidence that these structural changes occur at the same time psychologists observe a significant improvement in working memory (Reznick, Morrow, Goldman, & Snyder, 2004). These biological changes permit 1-year-olds to hold representations of experience in an active state for a longer time and to retrieve representations of events that occurred 10–30 s earlier (Kagan & Herschkowitz, 2005; Seress & Mrzljak, 1992; Witter, 1993).

Not surprisingly, these structural changes are accompanied by changes in power in the electroencephalogram (EEG) and ERPs. For example, a working memory task (Piaget's A not B problem) administered to 8-month-olds evoked changes in power across the entire cortex, whereas a working memory task administered to 4-year-olds was associated with more localized changes in power restricted to medial frontal sites and increased coherence between frontal and temporal–occipital sites (Bell & Wolfe, 2007). The various waveforms of the ERP also undergo a major change between 3 and 24 months (Jing & Benasich, 2006; Richards, 2003; Scott, 2006; Webb et al., 2005), and the amplitudes of the P2/N2 waveform to click sounds increase in a linear fashion between 1 and 12 months (Ohlrich & Barnet, 1972). In addition, the proportion of quiet sleep associated with sleep spindles (12–14 Hz) increases in precentral sites at 9–10 months (Tanguay, Ornitz, Kaplan, & Bozzo, 1975).

The brain continues to mature after the first birthday. Blood flow is greater to the right than to the left hemisphere during the opening 3 years but shifts to more predominant flow to the left hemisphere at about 4 years of age (Chiron et al., 1997). Synaptic density in the primary auditory cortex does not reach adult values until puberty; dendrites on neurons of the dentate nucleus of the cerebellum undergo intensive lengthening and extension, and the basal ganglia continue to develop during the 2nd year. Dopamine receptors in the caudate nucleus (especially D1 and D2 receptors) do not reach maximal density until the middle of the 2nd year and the neurons of Cortical Layer 3, which comprise the cells of the corpus callosum, increase in size during this interval (Huttenlocher & Dabholkar, 1997).

The concentration of the enzyme involved in the synthesis of acetylcholine increases sharply during the 2nd year when pyramidal neurons begin to express acetylcholinesterase in cell bodies and fibrillary networks (Black, 1991; Blokland, 1996). The innervation of Layer 3 pyramidal neurons by acetylcholinesterase and the growth of Layer 3 neurons probably contribute to the seminal advances of the 2nd year, especially the emergence of language, a moral sense, and self-awareness (Kagan, 1981; Mesulam & Geula, 1991). Finally, the human brain does not attain 90% of its adult weight until 7 or 8 years of age (Giedd et al., 1999), the density of D1 receptors in the basal ganglia does not attain peak density until 4–8 years (Seeman et al., 1987), the degree of coherence of various EEG frequency bands between frontal and occipital or temporal areas increases after the third birthday, and the latency to the peak value of the N170 waveform to faces decreases by as much as 10% between 5 and 7 years of age (Taylor, McCarthy, Saliba, & Degiovanni, 1999).

In sum, between the first and the eighth birthdays, the human brain attains peak synaptic density, maximal glucose uptake in the prefrontal cortex, peak concentrations of dopamine and norepinephrine receptors, myelination of long cortical tracts, coherence in the EEG, and maximal differentiation of dendrites in the hippocampus. It seems reasonable to suggest that these changes are accompanied by qualitative transformations of the cognitive functions of infants.

Final Summary

The most enthusiastic advocates of a return to nativism do not insist that the infants' concepts for number, physical impossibility, causality, or the permanence of objects are essentially the same as those of adolescents. The central suggestion in this article is that the perceptual representations that comprise schemata are to be distinguished from the conceptual structures involving semantic forms and inferences about events that were not experienced. Infants turn away from dissonant musical chords but do not possess the musician's concept of dissonance; infants who grasp an object placed in their palm do not understand the concept "mine." Spelke (1994), an influential advocate and sophisticated experimental psychologist, reminds us that there is no consensus as to when particular knowledge structures appear, how they are altered with growth and experience, what role the infants' representations play in the later development of thought and reason, and adds, wisely, that the infants' cognitive functioning has to differ from that of adults because "distinct knowledge systems are less interconnected" during the 1st year of life (Spelke, Vishton, & Von Hofsten, 1995, p. 177).

Hence, it is appropriate to ask why the notion that young infants possess conceptual talents resembling those of older children became attractive to a select cohort of developmental psychologists in such a short time. One speculative explanation is that there is a competition for dominance between the language networks of biology and those of the social sciences. The dramatic advances in molecular biology and neuroscience, which are to be celebrated, have led most biologists, but a smaller number of social scientists, to assume that the vocabulary of the brain sciences will prove to be more fruitful than the psychological concepts that emerge from brain activity and depend on the products of experience. This article has suggested that a construct purporting to explain a psychological competence as a process inherent in the infant's brain organization need not have the same meaning as one that explains a process requiring extensive experience. However, some younger scientists have become attracted to the language networks of biology and neuroscience because these domains have become challenging areas of inquiry that provide generous research funds to those who study the relation between biological and psychological outcomes. Scientists who study the relations between experience and psychological phenomena find it more difficult to gain support of their work. Even the most committed scientists are susceptible to the schedule of rewards. I suspect that some social scientists feel that the importance of their research is enhanced if their ideas and data can be classified as belonging to biology rather than psychology. The idea that mathematical and physical principles are represented in the brains of 6-month-olds seems to be a biological, rather than a psychological, fact.

A second reason is that psychologists have tried for many decades to specify the experiences that a maturing brain, with its biologically prepared sensory and motor skills, exploits as children develop new competences. Because investigators have not been as successful as they hoped, their frustration is reduced a little by declaring that the kernel of the conceptual ability was already present in the first half of the 1st year. If this suggestion were true, the difficult task of discovering the differences between the earlier and the later forms, and understanding how those differences were created, would recede into the shadows. If 4-month-olds already appreciate that some physical events are impossible, the fact that 3-year-olds possess a kernel of this principle becomes less of a mystery. However, this position is surprising in light of what biologists have learned about embryological development. The 3-week-old embryo possesses neither a convoluted cerebral cortex nor the structural changes that the secretion of steroid hormones will induce at a later time.

The next cohort of developmental psychologists interested in these questions should gather additional sources of evidence besides fixation time; these include ERPs, skin conductance, muscle tension, blood flow, changes in heart rate, smiling, and vocalizing. Second, they should try to discover, with cross-sectional or longitudinal designs, the experiences necessary for actualization of the competences in older children that might assume a simpler form in infants (Campos & Bertenthal, 1989). This evidence could illuminate the nature of the changes that occur between infancy and later childhood and clarify the degree of continuity or discontinuity between them.

If 2-year-olds cannot add the cardinal numbers 2 and 4 and do not know which door to open to retrieve a ball resting behind a visible occluder, it is possible that the apparently similar "knowledge" infants are presumed to possess is qualitatively different from that of the school-aged child. I agree with Aslin's (2000) suggestion that the nativist position remains viable until additional evidence clearly refutes or fails to reject this view. Additional research is required before psychologists can be certain of the degree of similarity in mechanism between the cognitive functions of infants and older children. My skepticism rests on the observation that it is rare, in any scientific domain, for a single measure to reveal all that is necessary to understand a phenomenon. Hence, it is reasonable to question the assumption that an increase in fixation time of a few seconds to an event that violates an acquired perceptual expectation, without any other evidence, is a sufficient basis for inferring that infants under 6 months possess a conceptual representation of number, physical impossibility, causality, or the permanence of objects that shares important features with the competences awarded the same name in older children.

This commentary endorses J. Kagan's (2008) conclusion that many of the most dramatic findings on early perceptual, cognitive, and social competencies are ambiguous. It supports his call for converging research operations to disambiguate findings from single paradigms and single response indices. The commentary also argues that early competencies must be placed into a longitudinal framework, thereby allowing researchers to (a) identify whether regressive phenomena play a role in skill development, (b) understand what functions (if any) given skills play in their precocious manifestations and whether these functions are comparable in later instantiations of skills, and (c) avoid rich interpretations by identifying how robust a suspected competency is across contexts.

With eloquence and tact, Kagan (2008) has dropped a gauntlet, challenging the major intellectual and empirical trends in infancy research of the past quarter century. He has offered a persuasive rejoinder to those in developmental psychology who assign adult-like cognitive competencies to the young infant and who as a result both deemphasize and distract the field from the study of developmental transformations essential for understanding the baby. In so doing, Kagan goes well beyond correcting erroneous impressions about the adequacy of the evidence for early competencies in the infant. He argues heuristically, laying out implicitly and explicitly a number of major new lines of research using a fundamentally different approach to studying the human infant. These new lines of research involve supplementing the study of origins of psychological processes with descriptions of qualitative developmental transitions in infancy and adulthood and explanations of how those qualitative transitions take place.

Kagan has made his points by delineating the methodological and metatheoretical problems inherent in the work on infant perceptual/cognitive precocities. He identifies serious errors in the cornerstone assumption of work on precocity: the implicit belief that "impossible" events are more novel than "possible" ones and that the more novel an event is, the greater the looking time. Kagan reminds us that the functional relation of looking time to novelty is an inverted-U function; consequently, the duration of looking can be either *greater* to a novel stimulus than to a familiar, *equal* to one another, or *less*—depending upon where in the inverted-U function the novel and more familiar stimuli fall. This methodological critique renders ambiguous almost all studies linking "possible" and "impossible" events to lesser and greater looking times. To Kagan's critique, we add that the infant's registration that a transitional probability has been violated is an inadequate basis to infer that an infant has a theory of gravity or of object permanence, just as an infant's growing appreciation of differential phoneme transitional probabilities at word boundaries is an inadequate basis to infer that an infant has a theory of language. Much of the past quarter century of research in infancy needs to be

---

reinterpreted, the issues about competencies need to be revisited, and widespread and incautious acceptance of claims for infant competencies need to be halted.

The ambiguity of inference about competencies is rendered yet more problematic by the paucity of converging research operations in "competent infant" research. Although the findings were never replicated, the methodology of Bower (1974), the father of the competent infant approach, provides exemplary illustration of converging research operations on the topic of early perceptual and cognitive competencies, especially depth perception. He claimed precocities in depth perception through the use of discriminated operant responding, avoidance reactions to looming stimuli, and reaching to a virtual object presented stereoscopically. Reporting findings that converged on consistent conclusions across paradigms, Bower provided a powerful case for precocious depth perception because these very different paradigms yielded the same conclusion. His methods stand as a textbook example of how an investigator should proceed to establish the validity of a conclusion about the presence and operation of an internal psychological process. Only the absence of replication kept his work from being definitive.

Sound converging research is necessarily more difficult than an initial research foray, so we are not surprised that competent infant research has made so few attempts at converging research and has not buttressed findings stemming largely from a single paradigm—habituation/dishabituation—and a single response index—one or another parameter of looking time. Consider, for example, the "violation of expectation" paradigm (e.g., Baillargeon, 1994; Wang, Baillargeon, & Brueckner, 2004). Despite alluding to the violation of expectancy paradigm as a "surprise" paradigm, this work never quantified the emotion of surprise facially, posturally, autonomically or with instrumental behaviors in the manner that Hiatt, Campos, and Emde (1979) did with older infants.

Studies of reaching in the dark (Clifton, Rochat, Litovsky, & Perris, 1991; Hood & Willatts, 1986; Robin, Berthier, & Clifton, 1996) show the advantage of converging research operations. These studies do yield some evidence for a rudimentary ability of 6-month-olds to keep in mind an absent object. However, even the work on reaching in the dark requires further converging research operations to hone in on object permanence, because. As conducted, such studies do not test the most important aspect of object permanence. Piaget's (1954) arguments on object permanence are intimately tied to means – ends behavior in relation to interference of the reach of a target by an obstacle or cover. In reaching in the dark, there is no intervening obstacle; there is no opportunity for the infant to place one action as subordinate (means) and a second one as superordinate (ends). Even if claims for precocious infant representational abilities ultimately prove true, it would be misleading on the evidence adduced to date to conclude that infants possess object permanence in the manner that is central to the theory that is supposedly being disproven. The same cautionary comment holds true for claims about rudimentary understanding of number concepts, imitation, or spatial awareness. At best, work to date on infant precocities has raised the possibility of competence in one skill (e.g., keeping in mind an absent entity for a few seconds) but has neither provided conclusive evidence for the existence of the precocity nor documented that the precocity plays a role in the more developed competency of the older child.

Kagan's critique goes well beyond documenting ambiguity of inference about competencies. The critique is also metatheoretical. He argues that the neglect of transformations evident in so much of the literature today incorrectly suggests a hypothetical continuity in development between early forms reported in the newborn or young child and later ones seen in the older toddler, child, and adolescent. He gives numerous instances of the difference between "schematic" levels of analysis that involve perception and simple memory, and semantic levels that imply greater organization and resistance to disruption by perceptual displays. His metatheoretical critique makes a powerful statement: Morphological similarities between early and later phenomena (such as "counting," imitation, or representation of hidden objects) do not imply similarity, let alone identity, of underlying process. Kagan insists that apparently similar earlier and later behaviors may mask different underlying mechanisms.

The present commentary builds on Kagan's article and points to new approaches to research. Our commentary depends heavily on the writings of Witherington (2007), Overton (1991), and Oppenheim (1981), whose publications on ontogenetic adaptations should be required reading for developmentalists. The main points we want to make are as follows:

1. There are continuities and discontinuities in development, losses as well as gains, reorganizations and transformations. The presentation of data from studies of a single age and a single paradigm is necessarily incomplete and, as we have noted before and will note again later, risk misleading the field.

2. The behavior of an infant at a given point/level of development cannot be assumed to provide evidence for a core competency leading to a well-developed final state. There may well be immediate functional consequences of behaviors shown at a particular phase of development that are adaptive *for that period*, without the competency having import for later behaviors. Additional evidence must be adduced that a competency gets built upon.
3. Development often consists of the hierarchical coordination of skills or component processes—the coordination yielding emergent outcomes. Such emergents represent reorganizations in form, wherein the emergent depends on prior competencies but does not "contain" them. The prior competencies take on qualitatively new, more general, and more flexible meanings.

Some Guidelines for Studying Development

In this section of our commentary, we interweave the three points just discussed into a set of guidelines designed to restore a developmental perspective to contemporary studies of infant competencies.

Guideline 1: Developmental Phenomena Are Embedded in Time: They Have a Forward Reference, a Contemporary Reference, and a Backward Reference

Development is not simply "change over time." To be truly developmental, the change must involve understanding how a phenomenon came about from the coordination of skills and processes present beforehand and how a phenomenon points to a future end state. To study a phenomenon developmentally, then, is to place it in the context of previous forms and potential subsequent forms (Oppenheim, 1981). Research on neonatal or precocious infant competencies is woefully lacking in this regard.

As we have already noted, contemporary competent infant researchers infer continuity in development from behaviors that are apparently morphologically similar at two very different points in time. This search for morphological similarities can lead to major errors. A good example of such an error is found in the work on neonatal imitation. The imitation seen in the newborn differs from that in older infants in many ways (see Jones, 2007, for an elaboration of this point), of which we discuss one: the restriction in scope (if not in existence; see Anisfeld et al., 2001) of behaviors like mouth opening and tonguing in neonates. Later, imitation is much more flexible, less stereotyped, and has a much broader "receptive field" than that of the newborn, extending well beyond simple oral behaviors. Imitation in the older infant occurs much more reliably and is much more robust to contextual variations, making later imitation far more capable of scaffolding communication. Moreover, to judge from Jones's (2007) recent report, neonatal imitative mouthing and tonguing largely disappear before the second half year of life, not to be seen again until 18 months of age and older. Where, then, is the continuity of a core competency for imitation and what happens to the parent–infant communication for which neonatal imitation is putatively the scaffold?

Is it preferable to conclude that there is indeed a loss of form and function between the weak and the ephemeral imitation that might exist in the newborn period and that shown in later infancy? Are the newborn skills still there, only remaining "hidden" (e.g., Thelen & Ulrich, 1991) or inhibited (Diamond, 1990)? Or, are there major transformations that take place in imitation across the first 2 years of life and thereafter evident only in as yet undone longitudinal studies designed to document what has been gained and what has been lost? We favor the third strategy, which is rich in potentially informative and unexpected findings, such as whether the development of imitation follows an ordinal sequence, and what mediates the broadening of the behaviors that an infant can imitate (see Uzgiris & Hunt, 1975).

Guideline 2: Context Affects the Breadth of Effect of Competencies

Research on infant competencies is notoriously weak in dealing with contextual factors that serve as boundary conditions for the manifestation of skills and create limitations of the generalizability of the behaviors. Consider the claim that 5-month-old infants possess the capacity to represent absent objects and to place two mental representations into spatial relation with each other (Baillargeon, 1994). This claim raises many more questions than it answers, questions that must be followed up to support the interpretation that the finding indicates a core competency. Otherwise, we have a mere snapshot in the developmental process—a snapshot that does not demonstrate how the infant at a given age arrived at the claimed precocity or how that phenomenon links up to later manifestations of "object permanence."

Let us review several of the outstanding issues that must be addressed before object permanence can be attributed to the 5-month-olds. Notice how constrained the testing paradigms used to demonstrate competencies are, how brief the demand is on the infant to "keep in mind" absent entities, and above all, as noted above, how lacking is description of how the precocious representation becomes linked to action later on, such as in means – ends behavior. Furthermore, the developmental background of the phenomenon has been lost; how is the object permanence of the 5-month-olds related to prior forms of reactions to objects that suddenly vanish? What is the mechanism by which precocious representation comes about? Do motoric skills play a role as inducers or facilitators of such representations, as they do at later ages (Kermoian & Campos, 1988)? For instance, does the new grasping skill of the 4- or 5-month-olds facilitate the ontogeny of representation because at this age, for the first time, a grasped object becomes occluded to sight but present to touch? We suspect that an analysis of the processes underlying early representations may reveal both how early representations are similar to and how they are different from, later and more complex representations. Such considerations about process are generally lacking. As a result, claims stemming from the study of precocious object permanence strike us as incomplete, even if we were to find the fundamental interpretation of looking time convincing.

Continuing with the theme of object permanence, we note how at older ages representation must become more enduring and more resistant to intrusions from new task demands. Impose an intermediate action between hiding and finding an object (i.e., make the representation serve a means – ends function), and the representation may become insufficient to guide behavior properly (Piaget, 1954). Change the posture of the infant between hiding and search and previously successful strategies may fall apart (Burger, 2004). The infant must have not only a representation of a hidden object but also the capacity to coordinate that representation with the act of removing a cover and then grasping the searched for object. Is it possible that the reported representational skill of the 5-month-olds is not sufficiently robust to mediate or play a role in these more cognitively demanding contexts? Is it possible that the memory of the 5-month-olds is weak and that any new task demand will disrupt the memory? And how does the 5-month-old's memory link up with the memory that mediates the complicated continuation of searching (lifting covers, looking all over the floor, shaking the container hiding the object, etc.) that a 14-month-old shows when he or she fails to find a toy where it has just been hidden (Ramsay & Campos, 1978)?

When viewed in this developmental light, the demonstration of the presence of a memory for spatial relations out of sight in a 5-month-old does seem to us strangely incomplete. The lacuna can be addressed in future research by adhering to the principle that processes typically have a precursor form and trend toward a more mature or well-developed end state. In addition, there must be recognition that contextual factors such as minimizing the task demands on the infant may facilitate the demonstration of apparent precocities and account for differences in performance by infants at different ages. Research keeping these points in mind is sorely needed. The 5-month-old's behavior, like that of the imitating newborn, must be placed into the developmental stream of time, with the investigator describing not only changes in behavioral outcomes with age but also (a) how behavior acquires a new level of organization with age or transformative events such as locomotion (Campos, 2006; Campos et al., 2000) and (b) how the infant's behavior trends toward a mature end state, described ahead of time. We also must understand how infants deal with perturbations they encounter in their environments and how alternative developmental pathways may be used to attain an end state (such as can occur in thalidomide infants; see Decarie, 1969; Kopp & Shaperman, 1973).

Guideline 3: There Are "Regressive" Phenomena in Development

No phenomena illustrate the need for embedding unsuspected competencies in developmental time better than those that show "regressive functions" in development. A regressive function refers to phenomena that are apparently present in the newborn and then become unobservable, and perhaps lost, only to emerge again at a higher level of function at a later age. These regressive phenomena include neonatal imitation, the newborn's grasp, the "empathic cry" of the newborn, postural compensation to patterns of optic flow, localization of sound, neonatal stepping, visual proprioception, and many others (Heimann, 2003). These regressive phenomena suggest that behaviors at one age that are apparently morphologically similar to those at later ages may in fact operate under rather different principles and may be controlled at one age by one neurophysiological process and at a later age by a different one (Gilmore, Hous, Petter, & Norcia, 2007). Alternatively, a set of behaviors can serve an adaptive function at one age, but the same or similar behaviors can serve a rather different function at a later age.

Regressive phenomena are well known to the developmentalist but are usually relegated to neonatal "reflexes." In fact, they apply to fairly mature reactions by the newborn. We will discuss two such regressive phenomena not usually considered as reflexes: the reach and grasping response and the postural response to peripheral optic flow.

Discontinuities in the reach and grasp response. When provided with sufficient head and trunk postural support, neonates engage in a form of reaching (actually "prereaching") behavior consisting of spontaneous forward arm extensions directed in the general direction of objects upon which visual attention is fixated. In the first few weeks of life, this prereaching activity is visually elicited, rather than visually guided. By that is meant that the newborn's reaction is triggered by vision (hence "elicited") but shows little behavioral flexibility (hence, not visually guided); by contrast, the behavior of the older infant shows modification of the path taken to the target of reach and an ability to adjust the response to different distal relations. The neonatal reach is typically accompanied by an opening of the hand, with fanlike extension of the fingers, but contact with objects is highly unreliable, with no attempt to grasp the objects (von Hofsten, 1982). Furthermore, hand opening in the context of prereaching acts as an extension of the arm movement synergy and not as an adaptive action in its own right; hand opening accompanies forward extension irrespective of whether the infant visually fixates an object. In agreement with the stance elaborated later in this commentary, von Hofsten (1982) has argued that the forward extension of reaching behavior in the newborn may differ from later developmental forms of reaching with respect to the functions it serves. Whereas reaching at 3–4 months is clearly in the service of *manipulation*, the earlier, visually elicited, reaches of the very young infant may function to *prepare the infant to orient or attend to, but not to manipulate*, an external object. Young infants' forward extensions, then, are functionally linked to looking as part of a general orienting response to objects. Thus, the forward extensions of 2-week-olds to an object may differ qualitatively in their functional significance relative to the same basic extensions (now integrated with grasping actions) of the 3-month-olds. In sum, that which appears morphologically similar at 1 week of age and 5 months of age proves to be functionally quite different across ages.

There is another important aspect of the reaching response that calls for caution among those who favor continuities in development. Over the course of the first 7 weeks of postnatal life, visually elicited reaches progressively decline in frequency as the young infant increases its visual inspection of objects, in the absence of any arm movements (von Hofsten, 1984). Between 2 and 3 months, however, reaching activity reemerges in frequency, but now forward extensions of the arm are accompanied by a fisted hand and characterized as swiping. After this period, around 4–5 months, infants begin again to open their hands as they reach for objects but now do so in the context of attempts to grasp objects that are visually fixated (von Hofsten, 1984). This visually guided or *goal-directed* reaching involves coordinated reaching and grasping activity and seems to be qualitatively distinct from the prereaching efforts that precede it. Neonatal reaching is thus not organized in the same way in the newborn and the 5-month-olds. Claiming continuities in this important skill of the child would be an error.

Discontinuities in visual proprioception. Another example of a phenomenon present in the neonate that becomes qualitatively transformed is the newborn infant's visual proprioception—the sense of self-motion produced by patterns of optic flow. Visual proprioception is what occurs when we experience induced and illusory self-motion when seated in a train: The movement of a train in the adjacent track creates a sense that one's self is moving and not the adjacent train. More generally, when there is optic flow moving toward a person in the visual periphery, the optic flow generates (a) a sense of self-motion in the direction opposite the movement of the optic flow and (b) a compensatory head, and later, total body, movement in the direction of the optic flow.

Newborns show backward head adjustments to optic flow moving toward the infant—an appropriate adaptive postural compensatory response to peripheral optic flow (Jouen, 1988). This demonstration is replicable (Jouen, 1990; Jouen, Lepecq, & Gapenne, 2000). However, as with reaching, the neonatal phenomenon appears to decline in effectiveness, only to return with renewed potency in the second half year of life. In the case of visual proprioception and peripheral optic flow, the catalyst for change proves to be locomotor experience.

Bertenthal and Bai (1989) documented that at 5 months of age, peripheral optic flow alone no longer elicits postural compensation, but it does at 9 months. Higgins, Campos, and Kermoian (1996) went on to show that crawling infants and prelocomotor infants of the same age having artificial "walker" experience respond appropriately to peripheral optic flow; prelocomotor infants of the same age as the other two groups do not—or do not do so as strongly. Furthermore, training in a powered mobility device brings about a heightened level of responsiveness to peripheral optic flow (Uchiyama et al., 2008). As with neonatal reaching, neonatal response to peripheral optic flow is evident, then may "hide" before the infant is 5 months of age, only to reappear at a higher level of organization at a later age in conjunction with the acquisition of another developmental skill—locomotion.

Guideline #4: Early Competencies May Serve Functions Quite Different From Later Ones

Oppenheim (1981) makes the point that a true developmental analysis requires the investigator to explore the contemporaneous functions that precocious organized behaviors serve. Our field honors in the breach this powerful developmental principle. We sometimes describe different levels of behavior in a skill domain, but we rarely speculate on, or test for, the adaptive function that each level of a skill has at one point in time, relative to the adaptive function that skill possesses later on.

One precocity in behavioral development, the so-called empathic cry of the newborn to the cry of another newborn, may illustrate Oppenheim's (1981) point well. As demonstrated in several labs and with different procedures, a newborn will cry to the wailing of another newborn but not to the cry of a chimpanzee, white noise, or the cry of an older child. As with neonatal reaching and visual proprioception, the empathic cry drops out, no longer evident at 5 months of age (Martin & Clark, 1982). Presumably, "empathic" reactions emerge again later, starting at 14 months of age, when infants show empathic instrumental behaviors to an adult "crying" in pain to a simulated injury (Dondi, Simion, & Caltran, 1999).

Our point in discussing the empathic cry is not simply to give one more illustration of regressive phenomena in development. Instead, our focus here is on the question: How does the neonatal cry to the cries of another infant have contemporary adaptive significance and how might the function of the cry for the newborn explain the presence of that skill early in life without there being a continuity with apparently similar processes occurring later on in life? Most contemporary studies on neonatal competencies do not consider what adaptive value the phenomenon of interest has at the age the infant is tested for the precocity. In the case of the neonatal cry, however, there is the possibility that a powerful adaptive function is being manifested by the infant crying to the cry of the other infant, but that the function is anything but empathic. Specifically, could it be that the function of the empathic cry is actually a competitive one? The possibility of such cries being competitive is premised on the fact that (a) crying by a neonate—any neonate—elicits the "let down" reflex of the mother, permitting nursing and (b) the cry of the target neonate can serve as a competitive call for the mother—now capable of nursing—to come and nurse her infant rather than someone else's infant. Proceeding with our argument, we wonder whether once the newborn period ends and a reciprocal relationship with the mother is established, the newborn's empathic cry loses its original competitive function and hence drops out of the infant's behavior repertoire. When an older child is later observed showing an empathic response to the mother or to another baby, this empathic behavior is a morphologically and functionally different reaction based on different developmental processes (Zahn-Waxler, Robinson, & Emde, 1992). In short, empathic phenomena in the neonate may have no relevance to empathy in the older child. Nevertheless, note that in our analysis, the empathic cry of the newborn does have major biologically adaptive significance in the neonatal period—as Oppenheim's (1981) principle would lead us to expect.

Concluding Comments

Clearly, this article is at best a beginning step toward a developmental analysis of behaviors that show apparent precocities. To talk about "concluding" is a bit like walking away from constructing a skyscraper when only a few floors have been erected. There is so much more to say about how one might proceed in taking a developmental perspective. For supplementation, we therefore recommend Witherington's (2007), Overton's (1991), and Oppenheim's (1981) more richly developed arguments. All three authors propose principles that are both more general and more abstract than those articulated here. As Witherington notes, developmental analysis begins with an understanding of the role of formal and final cause, as complements to the ready acceptance by developmentalists of efficient and material causes. When we explain behavior in terms of a particular stage or developmental level of organization, when we talk about the "organization of behavior" (e.g., Sroufe, 1996), we are appealing to formal cause—namely, how different skills are patterned in the here and now. When we talk about end points of development, we are appealing to final causes. Developmentalists do not take formal and final causes very seriously in the current state of the field, and as a result, we believe that our field suffers. To quote Murray (1991), "The earlier steps of stages in a developmental sequence of behaviors are made more intelligible by our knowledge of the end-point toward which they are progressing, even though the later periods cannot in any way be the efficient cause of the earlier events because of the unidirectional character of time" (p. 241). To

Murray's quote, we would add that we need to understand how behaviors are organized at each point in development, how they become progressively better coordinated, and how they function in the here-and-now adaptation of the individual (formal cause). A developmental perspective in its broadest sense then must consider both the increasingly complex patternings of behavior and the end states toward which development trends. It is instructive that current epigenetic approaches attempt just such a synthesis of material and efficient causes nested within final and formal ones. Epigenetic approaches call on all four levels of causality to fully explain how a phenomenon comes about with age.

We presented guidelines to help structure research toward a more organic and less static portrayal of development. In closing, we reiterate in different words the broad implications of our guidelines. These are that (a) many newborn and apparently precocious competencies may have nothing to do functionally with the mature competency and indeed may have no *contemporary* adaptive function at all (just as the lungs of the fetus are prepared for, but not typically called to, function), (b) some newborn competencies may be only a part of what will eventually be the mature one, and (c) a newborn competency may be thoroughly plastic (like a stem cell) and may be functional for different reasons at different points in the developmental stream. For all three reasons, assumptions about "core competencies" cry out for longitudinal investigations, which have been sorely lacking, and analyses of their contemporaneous and subsequent functions, which often are subject to neglect. As Kagan (2008) noted, the past quarter century of research on infant developmental precocities must be revisited and likely revised.

In Defense of Core Competencies, Quantitative Change, and Continuity

Paul C. Quinn
University of Delaware

J. Kagan (2008) urges contemporary developmentalists to (a) be cautious when attributing conceptual knowledge to infants based on looking-time performance, (b) constrain their interpretation of infant performance with multiple methodologies, and (c) reconsider the possibility that qualitative development may be the path by which perceptual infants become conceptual adults. This commentary outlines an account of conceptual development that adheres to two of the three Kagan provisos. It is (a) circumspect in the core competencies attributed to infants and (b) grounded in convergent measures including looking time, event-related potentials, computational modeling, and eye tracking, but (c) maintains that the transition from the perceptually based category representations of infants to the knowledge-rich concepts of adult is a continuous developmental process marked by quantitative change.

In a provocative article, Kagan (2008) has rebooted the vigorous debate that sprang up about a decade ago when Haith's (1998) article "Who Put the Cog in Infant Cognition? Is Rich Interpretation Too Costly?" was published by *Infant Behavior & Development*. The debate centers on the issue of what kinds of skills and knowledge can be attributed to infants based on their performance in experiments conducted with looking-time methodologies. Kagan contends that one is unlikely to observe adult competencies in infants and argues that looking-time results offer multiple interpretations, which need to be verified with convergent methodologies. Kagan also argues that the extent to which infant performance falls short of adultlike levels of competence should point investigators toward reembracing the notion of qualitative change as the path by which the nature of infant thought may be altered to attain the conceptual power of adult knowledge.

I agree with the argument that whatever mental structures are guiding infant performance in looking-time experiments, their content is unlikely to match the richness of the mature semantic concepts underlying adult competence. In addition, I agree with the argument that the multiple interpretations of infant looking time need to be evaluated further with convergent methodologies. It also seems reasonable to suggest that a vocabulary for describing infant performance be adopted that respects the immaturity of the infant's mental structures relative to those of adults. However, to develop this vocabulary in such a way that it emphasizes dissociation between infants and adults may not be warranted and to contend that qualitative change is the path to the end state of being fully developed may not be necessary. The remainder of the commentary will propose an account of early conceptual development that avoids rich interpretation of infant looking-time performance and uses multiple methodologies to further constrain that interpretation. But the account also argues that much of conceptual development can be accounted for by core competencies that when put into operation in the developing infant can begin to yield functional knowledge in a short period of time and that a continuous process of developmental enrichment marked by quantitative change may explain the transition from infant to child to adult concepts.

Perceptually Based Category Representations in Infants

Looking-time studies measuring the emergence of categorization during early development have demonstrated that young infants between the ages of 3 and 7 months will categorize animals such as cats, dogs, and horses (e.g., Mareschal & Quinn, 2001). The infants are presented with multiple instances from a common category during familiarization (e.g., cats) and then with a preference test pairing a novel instance from the familiar category (e.g., a new cat) with a novel instance from a novel category (e.g.,

a new dog). Categorization is inferred if infants generalize their familiarization to the novel instance from the familiar category and display a preference for the novel instance from the novel category.

Categorization Versus Discrimination

It is worth emphasizing that the animal stimuli presented to the infants were realistic photographic images. In the case of cats, the stimuli depicted different breeds in a variety of colors and stances. In fact, the stimuli from within a category were highly discriminable, an observation that underscores that the novel category preferences cannot be attributed merely to processes of perceptual discrimination between categories. The infants can discriminate between the different instances of the cats just as readily as they can discriminate between a cat and a dog, yet they are also able to look through this variation so as to group together the various cat images into a common representation that excludes the dog images. As Kagan (2008) notes, "Young infants and many animal species can discriminate between pictures of an elm tree and an elephant and between parallel and nonparallel lines. But this evidence does not mean that they possess the semantic concepts of plant, animal, or parallel" (p. 1609). I agree completely with Kagan's observation (is there anyone who would disagree?) but would also note that the categorization task presents infants with two novel stimuli in the preference test, thereby calling on infants to generalize from the familiarized instances to a novel instance from the same category and distinguishing the categorization task from a simple discrimination task.

Perceptually Based Category Representations Versus Perceptual Schemata

Being careful not to overinterpret infant performance, I have adopted the stance Kagan recommends in describing the mental structure guiding infant looking behavior with a construct that differs from the term that might be used to describe adult performance. That is, infant performance has been described as being mediated by "perceptually based category representations" rather than "concepts." This is to respect the fact that the infants at issue are just a few months of age, and they are responding to visual images presented in the laboratory. They do not "know" about cats and dogs in the way that adults know about their more abstract genetic and reproductive attributes (e.g., cats have cat DNA and give birth to kittens). At the same time, I see no reason to minimize the accomplishments of the infants by relegating the status of their representations to "perceptual schemata," thereby creating a dissociation between the terminology used to describe the performance of infants and adults participating in category learning tasks. As described by Kagan, "Schemata are used primarily to recognize events, places, and objects experienced in the past" (p. 1609). By contrast, an important feature of category representations, even if based on perceptual information, is that they allow the infant to "go beyond the information given" in terms of being able to generalize to novel instances not previously experienced.

A Convergent Measure

As a complement to the behavioral looking-time studies demonstrating category formation for the various animal species by infants, Quinn, Westerlund, and Nelson (2006) asked whether neural correlates of category learning by infants might be measurable. They did so by developing an event-related potential (ERP) analogue of the behavioral looking-time procedure. The infants were presented with 36 cat images followed by 20 novel cat images interspersed with 20 novel dog images. The results (i.e., the neural activations observed in different parts of the scalp up to a second and a half after stimulus presentation) were partitioned into four different conditions: Cats 1–18, Cats 19–36, novel cats, and novel dogs. The rationale is that if there is a neural signal that corresponds with category learning, then the responses to Cats 1–18 and the novel dogs (reflecting initial experience with exemplars of a category) should be equivalent. The responses to Cats 19–36 and the novel cats (reflecting a learned category of cats) should also be equivalent but different from the responses to Cats 1–18 and the novel dogs.

Of interest was a late slow wave component observed in the time window between 1,000 and 1,500 ms after stimulus presentation. In studies of recognition memory for individual stimuli in infants (Nelson, 1994; Reynolds & Richards, 2005), the amplitude of the slow wave has been associated with the differentiation of familiar and novel stimuli. In particular, a slow wave that returns to baseline has been associated with recognition of familiarity, whereas a slow wave that deflects away from baseline in the negative direction is associated with detection of novelty. The results from Quinn et al. (2006) were that a negative slow wave was observed over left occipital parietal scalp in the time window between 1,000 and 1,500 ms after stimulus onset in response to Cats 1–18 and novel dogs, whereas a slow wave that returned to baseline was observed for Cats 19–36 and novel cats. This analysis reveals that the infant's brain responded to novel cats with activity equivalent to that displayed for Cats 19–36. More generally, it points to the neural instantiation of a key behavioral indicant of categorization: responding to the novel as if it is familiar. That there is distinct brain activity corresponding to the formation of a category representation for the exemplars presented during familiarization (e.g., the cats) provides convergent evidence with the looking-time studies and indicates a neural preparedness in the first half year of life to represent category information on the basis of perceptual experience.

Quantitative Versus Qualitative Change

The studies of infant learning of animal categories suggest that young infants divide the world of objects into perceptual clusters that later come to have conceptual significance for adults. As such, the conceptual representations found later in development may be viewed as informational enrichments of the category representations that infants form on the basis of perceptual experience (Quinn & Eimas, 1997). For example, infants who are presented with exemplars of cats and horses are not experiencing these exemplars as an undifferentiated mass but rather as separate groups that fall into distinct representations. These representations might then serve as placeholders for the acquisition of the more abstract information that occurs beyond infancy, through language and more formal learning of the nonobvious attributes associated with semantic categories (Quinn & Eimas, 2000). Thus, over time, the perceptual placeholder representation for cats will come to include the information that cats eat tuna, hunt mice, have cat DNA, give birth to kittens, and are labeled as "cats," whereas the representation for horses will come to include the information that horses eat hay, carry heavy loads, have horse DNA, give birth to foals, and are labeled as "horses." The acquisition of this additional information serves to enrich the original perceptually based category representations to the point that they attain the richness of the more mature conceptual representations of children and adults (Quinn, 2004). By this view, what changes as concepts mature is the content of the representations rather than the processes underlying their development (Madole & Oakes, 1999; Rakison & Poulin-Dubois, 2001).

We have also been careful not to overinterpret our category learning studies as indicating that infants are forming concepts that they leave the lab with and then carry around in their heads for everyday usage. The claim is that infants are demonstrating perceptual grouping or clustering abilities in the laboratory that are presumably engaged when infants encounter cats and horses in the course of experience in the world outside the laboratory (or images of them as depicted in videos and picture books). The latter representations are those believed to be the ones that serve as the supports for the acquisition of the nonobvious attributes that occurs beyond the infancy period.

Against Dissociating the Perceptual From the Semantic

I agree with Kagan's (2008) major claim that "perceptual competences" can be distinguished from "conceptual structures," but I also disagree with the assertion that qualitative change need be the path to get from one to the other. More generally, I disagree with the idea that the "physical features" of events should be separated from their "meaning." Even the most conservative theorists of cognitive development would grant that infants have operational perceptual input systems and a general learning mechanism to acquire a database of information about objects in the world. And that knowledge may be perceptual in nature. In the case of animals, stored data may include information about faces, coloring, skeletal appendages, a body shape bounded by curved contours, movement patterns, and species-specific sounds of communication. Kagan is strangely silent on the idea that powerful learning mechanisms provided with such perceptual input can acquire knowledge previously thought to be part of the infant's conceptual endowment (Elman et al., 1996). Such mechanisms, instantiated in the form of connectionist learning systems that provide yet another source of convergent evidence for those interested in explicating the mental status of infants, have provided important in-principle demonstrations that a single network (and hence a single system of representation) can produce a broad-to-narrow trajectory for category learning that was once thought to provide a distinctive signature for learning concepts separately from percepts (Quinn, 2002; Quinn & Johnson, 1997; cf. Mandler, 2000). Notably, the ERP evidence described earlier in which infants were simply provided with perceptual experience with visual images of cats and dogs also produced neural evidence for learning the more global category (cat + dog) prior to separating cats and dogs into distinct groupings (Quinn et al., 2006).

These observations raise the question of whether perceptual information should be dissociated from semantic categorization as Kagan and others have contended (Carey, 2000; Mandler, 2000). An alternative view (one that I embrace) is that knowledge about the perceptible parts and properties of objects can be semantic knowledge (see also Murphy, 2002, in press). One could not have much of a concept of cats, for example, without knowing what they looked like and what parts they had. Concepts must include perceptual information or else they would not be very helpful. It is hard to imagine how a child could even map the more abstract attributes onto their correct object referents without having category representations available from perceptual experience to serve as support structures. Even schoolchildren learning about biology must be able to recognize the Birman lying on the sofa, the long-haired gray Maine Coon sitting in the window across the street, and the short-haired orange tabby that just began patrolling in the yard next door as instances of "cats."

By this view, it becomes difficult to envision that the concepts formed by infants from perceptual experience are simply cast aside when a later concept that is imbued with more abstract information becomes available. It is important to acknowledge that this view does not deny that in some instances, more abstract information can supplant perceptual information when the two sources of information are placed in competition as determinants of category identity (Keil, 1989; Plunkett, Hu, & Cohen, 2008). This type of evidence has been used to support an "essentialist" view of concept development (Gelman, 2003). However, although "essentialist" arguments have been forceful in the literature, Hampton, Estes, and Simmons (2007) have actually presented cases in which a majority of research participants weight characteristic perceptual features more heavily than defining essentialist features in decisions about category identity, thereby suggesting that at least in some instances information about perceptual properties is considered just as semantic as information about genetics. Moreover, if one accepts the argument that perceptual information may be meaningful, then the difference between perceptually and conceptually based concepts is less clearly a qualitative one. Indeed, in nature, perceptual (form) and conceptual (function) information are often correlated and experiments designed to tease apart whether perceptual or conceptual information is the more potent determinant of categorization behavior may serve only to perpetuate what is arguably a false dichotomy. Instead, the way forward may be to explain how perceptual and conceptual knowledge are integrated (not dissociated) to form mature concepts (Murphy, 2002, in press; Quinn, 2004).

A Role for Biases

The account of category development offered in the present commentary, like that offered in Kagan's (2008) target article, has attempted to avoid radical nativist solutions that rely on innate knowledge, but it does recognize that there are likely to be constraints or preexisting biases of a general nature that help make the rapid development of categorization possible. Biases may assist infants in solving the nontrivial problem of determining which features should be selected for determining category membership. And while the evidence reviewed indicates that young infants can learn category representations on the basis of perceptual experience, it does not inform us as to the particular features the infants use to form the category representations. The answer to this question is not obvious, given that the exemplars from the various nonhuman animal categories possess a number of common attributes such as a head, torso, four legs, and a tail.

Quinn and Eimas (1996) examined infants' abilities to categorize cats versus dogs when provided with the whole stimuli, just the heads (with the bodies occluded) or just the bodies (with the heads occluded) during both the familiarization and the preference test portions of the experiment. The results were that the infants categorized when presented with either the whole stimuli or just the heads but not when presented with just the bodies. These findings indicate that the head provided a sufficient basis for the infants to categorize cats versus dogs. The conclusion of Quinn and Eimas (1996) was bolstered by an additional study in which infants were familiarized with whole cat or dog images and then preference tested with hybrid stimuli (i.e., cat head on dog body vs. dog head on cat body; Spencer, Quinn, Johnson, & Karmiloff-Smith, 1997). Infant preference during test followed the direction of the novel category head. Interestingly, adults also seem to emphasize the head when representing animal species (Reed, McGoldrick, Shackelford, & Fidopiastis, 2004).

Use of the head could arise from a biasing mechanism that directs infant attention to the head information that is present in a visual scene (Johnson & Morton, 1991). It is also possible that the infants simply learn during the course of experience with the exemplars that the head is the most diagnostic part of the stimulus. In other words, the head feature may be flexibly created as the basis for the category representation in an online fashion (Quinn, Schyns, & Goldstone, 2006). To determine whether infants used the head because of a bias or because of online learning, Quinn, Doran, Reiss, and Hoffman (in press) used an eye-tracking methodology to measure the eye fixations of infants as they scanned the visual images presented in the categorization task. On the assumption that stimulus regions used for categorization will be preferentially fixated over those not used, it was reasoned that if the head preference results from a biasing mechanism, then infants should fixate more on the heads than on the bodies of the exemplars throughout the course of the familiarization portion of a category learning procedure. Alternatively, if the infants learn that the head is the most diagnostic region of the stimuli, then the head preference should emerge during the course of the familiarization trials. The major finding was that throughout the course of the familiarization trials, the infants were shown to have a marked preference for fixating the head that was present during the whole of familiarization.

The results are consistent with the idea that the reliance on the head for the categorical parsing of cats and dogs arises from a biasing mechanism. However, one could still argue that infants are simply orienting to the head because it contains high contrast internal features, and infants are attracted to the most visible portion of the stimulus (Banks & Salapatek, 1981). To address this possibility, a control study was undertaken that repeated the eye-tracking version of the category familiarization procedure but with stimulus images that were inverted (Quinn et al., in press). If the head preference resulted from infants' simply orienting to the most visible portion of the stimulus, then it should still be observed with inversion. However, if the infants orient to the head because of a bias that is in place to facilitate face recognition, then one would not expect it to be present with stimulus inversion, given that inversion changes the normal configuration of facial features, and faces are believed to be recognized on a configural basis. The major finding from the control study was that fixations to the head region of the stimuli were small when compared with fixations to the body.

The inverted control results provide evidence that infants use the head to categorize upright cat and dog images because of a biasing mechanism that responds to face information. This type of bias could facilitate conceptual development by allowing infants to differentiate categories that have faces (e.g., animals) and those that do not (e.g., furniture), as well as partition classes marked by distinctive facial make ups (e.g., cats vs. dogs). More generally, a bias of this nature may aid infants in selecting from among various features that are potentially available in the input (i.e., head or body), and in this way "set the system on the trajectory of learning" (Thelen & Smith, 1994, p. 315). Such biases may be especially important in determining the course of concept acquisition in a system that is otherwise characterized by flexibility.

Concluding Comments

This commentary has outlined an account of concept development that adheres to the guidelines set forth by Kagan (2008) in terms of being (a) cautious about the skills and knowledge attributed to infants and (b) based on evidence that converges from multiple methodologies (i.e., looking time, ERPs, computational modeling, and eye tracking). However, in contrast with Kagan, the account maintains that the perceptually based category representations of infants should not be dissociated from the knowledge-rich concepts of adults. Rather, the latter grow out of the former based on a continual process of enrichment in which category representations that are initially based on perceptual attributes come to incorporate nonobvious attributes acquired through informal and formal tuition and language. From this perspective, infants may begin to form categories based on core competencies consisting of functioning perceptual systems (including that for language) and a general learning mechanism (that can represent within-category similarity and between-category dissimilarity) that is facilitated in its operation by biases to attend to some inputs more so than others. Such competencies equip infants with the ability to form functional category representations that, although not adultlike in their initial form, will become adultlike during continuous real-time development that occurs in day-to-day interactions with a structured environment. Infants are endowed with the tools to build a foundation for conceptual development, rather than with a preconceptual form that will be shed once metamorphosis provides mature concepts.
